THE
EDINBURGH ENCYCLOPÆDIA;

CONDUCTED BY

DAVID BREWSTER, LL.D.

F. R. S. LOND. AND EDIN. AND M. R. I. A.

CORRESPONDING MEMBER OF THE ROYAL ACADEMY OF SCIENCES OF PARIS, AND OF THE ROYAL ACADEMY OF SCIENCES OF PRUSSIA; MEMBER OF THE ROYAL SWEDISH ACADEMY OF SCIENÇES; OF THE ROYAL SOCIETY OF SCIENCES OF DENMARK; OF THE ROYAL SOCIETY OF GOTTINGEN, AND OF THE ROYAL ACADEMY OF SCIENCES OF MODENA; HONORARY ASSOCIATE OF THE ROYAL ACADEMY OF SCIENCES OF LYONS; ASSOCIATE OF THE SOCIETY OF CIVIL ENGINEERS; MEMBER OF THE SOCIETY OF THE ANTIQUARIES OF SCOTLAND; OF THE GEOLOGICAL SOCIETY OF LONDON, AND OF THE ASTRONOMICAL SOCIETY OF LONDON; OF THE AMERICAN ANTIQUARIAN SOCIETY; HONORARY MEMBER OF THE LITERARY AND PHILOSOPHICAL SOCIETY OF NEW YORK, OF THE HISTORICAL SOCIETY OF NEW YORK; OF THE LITERARY AND PHILOSOPHICAL SOCIETY OF UTRECHT; OF THE PHILOSOPHICAL SOCIETY OF CAMBRIDGE; OF THE LITERARY AND ANTIQUARIAN SOCIETY OF PERTH; OF THE NORTHERN INSTITUTION, AND OF THE ROYAL MEDICAL AND PHYSICAL SOCIETIES OF EDINBURGH; OF THE ACADEMY OF NATURAL SCIENCES OF PHILADELPHIA; OF THE SOCIETY OF THE FRIENDS OF NATURAL HISTORY OF BERLIN; OF THE NATURAL HISTORY SOCIETY OF FRANKFORT; OF THE PHILOSOPHICAL AND LITERARY SOCIETY OF LEEDS, OF THE ROYAL GEOLOGICAL SOCIETY OF CORNWALL, AND OF THE PHILOSOPHICAL SOCIETY OF YORK.

WITH THE ASSISTANCE OF

GENTLEMEN EMINENT IN SCIENCE AND LITERATURE.

UNIVERSITY OF TORONTO LIBRARY

IN EIGHTEEN VOLUMES.

VOLUME VI.

EDINBURGH:
PRINTED FOR WILLIAM BLACKWOOD;
AND JOHN WAUGH, EDINBURGH; JOHN MURRAY; BALDWIN & CRADOCK;
J. M. RICHARDSON, LONDON; AND THE OTHER PROPRIETORS.

M.DCCC.XXX.

THE

EDINBURGH ENCYCLOPÆDIA.

CHEMISTRY,

History.

Is the science which treats of those events or changes in natural bodies, that are not accompanied by sensible motions. Its object is to ascertain the constituents of bodies, and the laws by which the simple atoms of matter unite together and form compounds.

Origin.

Neither the origin nor primitive meaning of the word *Chemistry*, in Greek χημια, or χημεια, is accurately known. That it was used by the Greeks, at least soon after the commencement of the Christian era, is certain; and many reasons coincide to render it probable that it was of Egyptian origin.

It is certain, that the χημια or *chemistry* of the ancients, was the name of an art of some kind or other. Suidas, a Greek writer of the ninth century, mentions this particularly in his Lexicon, under the word χημεια. He informs us, that it was an Egyptian art, practised at least as early as the third century: for Dioclesian, he tells us, ordered all the chemical books of the Egyptians to be sought out and burnt, because they had rebelled against him.

Original meaning.

A great many circumstances, which it would be tedious to adduce here, render it probable, that the word *chemistry*, among the Egyptians, was, at a very early period, nearly equivalent to our phrase *natural philosophy* in its most extensive sense, and comprehended all the knowledge of natural objects which they possessed. It is well known, that among the Egyptians all science was confined to the priests, who, considering it as a sacred deposit, took every precaution to conceal it from the people. It is possible, that this was the reason why natural philosophy got from them the name of *Chemistry*, which, in Plutarch's opinion at least, implied the *hidden* or *secret science*.

Of the progress which natural philosophy had made among the Egyptians, it is impossible for us at this distance of time to judge. The secrecy which they observed, precluded their improvements from being fully detailed by other nations; and all their genuine records and writings have been lost and destroyed in the shock of the numerous revolutions to which that hapless nation has been subjected. Some gleanings may indeed be gathered from the writings of Herodotus, Plato, Diodorus Siculus, Plutarch, and other Grecian philosophers, who were indebted for their information to the Egyptian priests, and from Eusebius, who has preserved some traces of their writings. From these gleanings, and from the lamp of philosophy which they kindled in Greece, it is evident that they had made some progress in the mathematical sciences; but it cannot be inferred, that they were acquainted with that branch of science which we at present call *chemistry*. They were, indeed, acquainted with various chemical facts; but these had neither been classified nor generalized.

New meaning.

In process of time, the word *chemistry*, as has been the case with many other terms, (the English word *physician*, for instance,) seems gradually to have acquired a more limited and precise signification; and instead of implying the whole of *natural philosophy*, as was originally the case, to have been confined to the *art of working metals*. This gradual change seems to have been, in a great measure, owing to the great importance attached by the ancients to the art of working metals. The founders and improvers of it were considered as the greatest benefactors of the human race; statues and temples were dedicated to their honour; and mankind, in the transports of their gratitude, raised them above the level of humanity, and enrolled them in the number of the gods.

How long the word *chemistry* retained this new signification, we do not know with accuracy. But in the time of Dioclesian, as Suidas informs us, it had acquired another and still more limited meaning, namely, the *art of making gold and silver*. The cause of this new limitation, and the origin of the opinion that gold can be made by art, are equally unknown. The art appears to have been cultivated with considerable eagerness by the Grecian ecclesiastics, to have passed from the Greeks to the Arabians, and by the Arabians to have been brought in-

The Alchymists.

to the west of Europe. Those who believed in it gradually assumed the form of a sect, under the name of *Alchymists*, a term which is supposed to be merely the word *chemist* with the Arabian article *al* prefixed. Thus the word *chemistry*, originally the same with natural philosophy, was at last, in consequence of a very whimsical revolution, applied solely to the *art of making gold*.

The alchymists laid it down as a first principle, that all the metals are composed of the same ingredients; or rather they affirmed, that the principles which compose gold exist in all the metals, contaminated indeed with various impurities, but capable, by a proper purification, of being brought to its perfect state. The great object, therefore, of their researches, was to find out the means of producing this purification, and consequently of converting the baser metals into gold. The substance which possesses this wonderful property they called *lapis philosophorum*, or the *philosophers' stone*. And many of them boasted, that they were in possession of this grand instrument.

Chemistry, as the term was used by the alchymists, was the *art of making the philosophers' stone*. They affirmed, that this art was above the reach of the human capacity; and that it was made known by God to those happy sages only whom he peculiarly favoured. The fortunate few who were acquainted with the philosophers' stone called themselves *adepti, adepts*, that is, persons who had got possession of the secret. This secret, they pretended, they were not at liberty to reveal, affirming that dire misfortune would fall upon that man's head who ventured to disclose it to any of the sons of men, without the clearest tokens of the divine authority.

The alchymists, in consequence of these notions, made it a rule to keep themselves as private as possible. They concealed, with the greatest care, their opinions, their knowledge, and their pursuits. And in their communications with each other, they adopted a mystical and metaphorical stile, and employed peculiar figures and signs, that their writings might be understood by the adepts only, and might be entirely unintelligible to common readers.

Notwithstanding all these obstacles, a great number of alchymistical books made their appearance during the dark ages; many of them under the real names of the authors, but a still greater number under feigned titles, or ascribed to the celebrated sages of antiquity. Though, during the whole of this period, the art of printing was unknown, and books consequently were multiplied with great labour and expence, this does not seem to have much lessened the number of alchymistical tracts. They must, therefore, have been bought up with eagerness, even by those who had no pretensions to the title of adepts; but who were buoyed up by the delusive hopes of becoming masters of the grand secret, and of suddenly rising by its assistance to affluence and distinction.

How far the alchymistical sect had extended among the ancients, or whether it had assumed the form of a sect, it is impossible to say. Traces of it appear among the Arabians, who turned their attention to literature soon after the conquest of the caliphs, and who communicated to our barbarous ancestors the sacred seeds of science. The principal chemical writers among the Arabians were Geber and Avicenna; and in their writings, such of them at least as we have reason to consider as authentic, there appears but little of that mysticism and enigma which afterwards assumed a systematic form.

The alchymists seem to have been established in the west of Europe at least as early as the 8th century. Between the 11th and 15th centuries, alchymy was in its most flourishing state. The writers who appeared during that period were sufficiently numerous, and very different from each other, both in their style and abilities. Some of their writings are totally unintelligible, and bear a stronger resemblance to the reveries of madmen, than to the sober investigations of philosophers. Others, if you make allowance for their metaphorical style, are written with comparative plainness, display considerable acuteness, and indicate a pretty extensive acquaintance with natural objects. They often reason with great accuracy, though generally from mistaken principles; and it is not unfrequently easy enough to see the accuracy of their experiment, and even to point out the particular circumstance which led to their wrong conclusions.

The principal alchymists who flourished in Europe during the dark ages, and whose names deserve to be recorded, either on account of their discoveries, or on account of the influence which their writings and example had in determining the public taste, were Albertus Magnus, Arnoldus de Villa Nova, Roger Bacon, Raymond Lully, and the two Isaacs of Holland.

Albertus Magnus.

Albertus Magnus was born in the year 1205, and died in 1280. He was a German, and, during the early part of his life, was so remarkable for his dulness, that he became the jest of his acquaintances. When about 17, he appeared at the university of Paris, where he studied with eclat, and where afterwards he obtained the title of *doctor*. He joined the order of Dominican Monks at Cologne, and was also bishop of Ratisbon. His works are very numerous; but those relating to chemistry are only three tracts. 1. A treatise entitled *De Alchymia*, in which he gives a very distinct account of all the chemical substances known in his time, and of the manner of obtaining them. He describes also, very concisely and clearly, the different instruments then employed by chemists, and the various operations which they had occasion to perform. This treatise, therefore, is of considerable value, because it exhibits with fidelity the state of chemistry in the 13th century. Towards the end, indeed, he falls into the common cant of the alchymists; but even then he uses but little of their ambiguous and metaphorical language. 2. His second treatise is on *Minerals*, and is equally plain and sensible. 3. If the third treatise, entitled *Lilium de Spinis Evalsum*, be genuine, it must have been written at a very different period of life; for it is infinitely inferior to the two others.

Thomas Aquinas.

Albertus, during one period of his life, taught publicly in the university of Paris, where he is said to have had for a pupil the celebrated Thomas

Aquinas, who afterwards wrote several treatises on alchymy, not inferior, in point of mysticism, to the other works of that renowned divine. There are, however, several words and phrases (*amalgam*, for instance) still retained in chemistry, which make their first appearance in his works. And his theories, which are ingenious enough, tend not a little to elucidate the data on which the alchymists went. We find, too, in him the commencement of that combination of astrology and alchymy, which makes so conspicuous a figure in the writings of his successors.

Roger Bacon.

At the same time with Albertus, lived Roger Bacon, by far the most illustrious, the best informed, and the most scientific of all the alchymists. He was born in 1224, in the county of Somerset in England; studied at Oxford, and afterwards at Paris. He became a cordelier friar, and, devoting himself to philosophical investigations, his discoveries, notwithstanding the pains which he took to conceal them, made such a noise, that he was accused of magic, and his brethren in consequence threw him into prison.

His writings display a degree of knowledge and extent of thought scarcely credible, considering the time when he wrote. In his small treatise, *De Mirabili Potestate Artis et Naturæ*, he begins by pointing out the absurdity of believing in magic, necromancy, charms, or any of those similar opinions which at that time were universally prevalent. He points out the various ways in which mankind are deceived by jugglers, ventriloquists, &c.; mentions the advantages which physicians may derive from acting on the imaginations of their patients, by means of charms, amulets, and infallible medicines; affirms that many of those things which are considered as supernatural, are merely so because mankind in general are unacquainted with natural philosophy. To illustrate this, he mentions a great number of natural phenomena which had been reckoned miraculous, and concludes with several secrets of his own, which he affirms to be still more extraordinary imitations of nature. These he delivers in the enigmatical stile of the times, induced, as he tells us, partly by the conduct of other philosophers, partly by the propriety of the thing, and partly by the danger of speaking too plainly. One of these secrets is a description of gunpowder, in language which cannot be mistaken. This was more than a century before Swartz, the German, who got the credit of the discovery, even existed.

Arnoldus de Villa Nova.

Arnoldus de Villa Nova lived at the same time with Roger Bacon. He was a physician, and seems to have been born at Villeneuve, a village in Provence, about the year 1240. He travelled through Spain, France, and Italy, and afterwards taught publicly in the university of Montpellier. His reputation as a physician was so great, that his attendance was requested in dangerous cases by different kings, and even by the Pope himself. He was skilled in all the sciences of his time, and was besides a proficient in Greek, Hebrew, and Arabic. When at Paris he studied astrology, and calculating the age of the world, found that it was to terminate in the year 1335. The theologians of Paris exclaimed against this and several of his other opinions, and condemned our astrologer as a heretic. This obliged him to leave France; but the Pope protected him. He died in 1313, on his way to visit Pope Clement V. who lay sick at Avignon. He has got the credit, (though, as far as appears, without deserving it,) of the discovery of spirit of wine and oil of turpentine. But he seems to have been one of the first that introduced these substances into pharmaceutical preparations. All his life long he was passionately devoted to alchymy. His writings on the subject are numerous. They all treat of the philosophers' stone, and are much more obscure than those of his predecessors; though it must be acknowledged that some important facts now and then occur in them. Perhaps the most curious of his tracts is his *Rosarium*, which is intended as a compend of all the alchymy of his time. It is divided into two parts: The first, which treats of the theory of the art, is plain enough; but the second, on the practice, which is subdivided into 32 chapters, and which professes to teach the method of making the philosophers' stone, is in several places unintelligible.

Raymond Lully.

Raymond Lully, who was born at Barcelona in 1235, was a disciple of Arnold, though they were both nearly of the same age, and died almost at the same time. The history of Raymond is very obscure. According to some, he was at first a profound logician, but, being disgusted with the vanity of disputing without end about trifles and absurdities, he turned the whole of his attention to alchymy. He afterwards travelled through France, Germany, and England; and, if some accounts are to be credited, he was at last stoned to death in Africa for preaching Christianity. His chemical writings are very numerous; but the whole of them are so obscure, and abound so much in ridiculous whims and absurdities, that they hardly deserve the labour of a perusal. He seems to have been the first who introduced those hieroglyphical pictures or symbols, which afterwards appeared in such profusion in the writings of the alchymists. He was, however, the discoverer, or at least the first describer, of some very important chemical agents.

J. I. Hollandus.

John Isaac Hollandus, and his countryman of the same name, were either two brothers, or a father and son. They were born in Stolk, a village in Holland, it is supposed in the 13th century. They wrote various treatises on chemistry, remarkable, considering the time when they lived, for clearness and precision. They describe all their processes with accuracy, and even give figures of the instruments which they employed. This renders their works very intelligible; and they deserve attention, because they exhibit the clearest proofs that many of the processes supposed of much more modern date were well known to them.

These are the principal alchymistical writers. It would be tedious and useless to enlarge the catalogue, as the greater number of their writings are remarkable for nothing but obscurity and absurdity. They all boast that they are in possession of the philosophers' stone; they all profess to communicate the method of making it; but their language is enigmatical, that only the wise may receive instruction, and that they may assist those adepts alone who are favoured with illumination from heaven. Their writings, in those benighted ages of ignorance, gained implicit credit, and the covetous were filled with ridiculous desires to enrich themselves by means of their discoveries. This laid the unwary open to the tricks of a set of impostors, who went about the world pretending that they were in possession of the secret of the philosophers' stone, and offering to communicate it to others for a suitable reward. Thus they contrived to get possession of a sum of money, and afterwards they either made off with their booty, or tired out the patience of their pupils by intolerably tedious, painful, expensive, and ruinous processes. It was against these men that Erasmus directed his well known satire, entitled *The Alchymist*. The tricks of these impostors gradually exasperated mankind against the whole fraternity of the alchymists. Books appeared against them in all quarters, which the art of printing, just invented, enabled the authors to spread with facility: The wits of the age directed against them the shafts of their ridicule; men of science endeavoured to point out the impossibility, or at least the infinite difficulty, of the art; men of learning rendered it probable that it never had been understood; and men in authority endeavoured, by laws and by punishments, to save their subjects from the talons of impostors.

Basil Valentine.

The chemists, of whom we have hitherto spoken, confined their researches chiefly to the metals and to the method of making gold; throwing out, however, occasional hints of the importance of their art in medicine. But the first man who formally applied chemistry to medicine was Basil Valentine. He is said to have been born in 1394, and to have been a Benedictine monk at Erford, in Germany. He wrote various treatises on chemistry, in all of which he applies it to medicine. The most important and famous of them, is his *Currus triumphalis Antimonii*, in which he celebrates the virtues of antimonial medicines, of which he had been the original discoverer. He first taught the doctrine, that all substances are composed of *salt*, *sulphur*, and *mercury*, which makes so prominent a figure in the writings of some of his successors.

Chemists had for ages hinted at the importance of discovering a universal remedy, which should be capable of curing, and even of preventing, all diseases; and several of them had asserted, that this remedy was to be found in the philosophers' stone; which not only converted base metals into gold, but possessed also the most sovereign virtue, and was capable of curing all diseases in an instant, and even of prolonging life to an indefinite length, and of conferring upon the adepts the gift of immortality upon this earth. This notion gradually gained ground, and the word *chemistry*, in consequence, at length acquired a more extensive signification, and implied not only the *art of making gold*, but the *art* also of *preparing the universal medicine*. Just about the time that the first of these branches was sinking into discredit, the second, and with it the study of chemistry, acquired an unparalleled degree of celebrity, and attracted the attention of all Europe. This was owing to the appearance of that very extraordinary man Theophrastus Paracelsus.

Paracelsus.

He was born in 1493, near Zurich, in Switzerland. His father, who was a medical practitioner, instructed him in physic and surgery. Conceiving a passion for alchymy, he was put under the care of Trithemius, abbot of Spanheim, and afterwards of Sigismund Fuggerus, from whom he acquired the practical part of the art. Afterwards he visited all the universities of Germany, Italy, France, and Spain, and travelled through almost every country in Europe; consulting indifferently, physicians, barbers, old women, conjurers, and chemists. At the age of 20 he was taken prisoner by the Tartars, and carried before the Czar of Russia, whose son he accompanied in an embassy to Constantinople; where, as he tells us, he was first let into the secret of the philosophers' stone. He now applied himself to the practice of medicine with so much success, that he acquired, in consequence, a very great reputation. The venereal disease had, a little before, made its appearance in Italy, and was now carrying its ravages over Europe, and baffling the feeble attempts of the regular physicians of the times. Paracelsus, previously instructed by Carpus of Boulognia in the method of treating it by means of mercury, cured that formidable disease wherever it presented itself, with comparative ease, and with the most unbounded applause. Opium, too, which he employed with freedom, enabled him to cure, or at least to palliate, many painful disorders.

In the 34th year of his age, when his reputation was at its height, he was appointed by the magistrates of Basle to deliver lectures in their town, and thus was the first public professor of chemistry in Europe; for before that time, the science was not taught in any university. In two years he quarrelled with the magistrates about a medical fee, and left the city. He rambled up and down the country, his disciples gradually forsook him, he sunk into the deepest dissipation, being scarcely ever sober, and never changing his clothes, not even during the night. At last, in the month of September 1541, he died at Salzburg, after a few days illness, in the 47th year of his age. Though he boasted all his life long that he was in possession of the universal medicine, which he called *elixir proprietatis*, by which he could not only cure all disorders, but prolong his own life to an indefinite length, and he actually talked of living to the age of Methuselah.

It is not necessary to draw any character of this extraordinary man. That he was an impostor, and boasted of secrets which he did not know, cannot be denied; that he stole many opinions, and even facts, from others, is equally true; his arrogance was insupportable, his bombast ridiculous, and his whole life a continued tissue of blunders and vice. At the same time, it must be acknowledged that his talents were great, and that his labours were not entirely useless. He contributed not a little to dethrone Galen and Avicenna, who at that time ruled over medicine with absolute power, and to reinstate Hippocrates on that chair from which he ought never to have risen. He certainly gave chemistry an eclat which it did not before possess; and this must have induced many of those laborious men who succeeded him to turn their attention to the science. Nor ought we to forget, that, by carrying his speculations concerning the philosophers' stone and the universal medicine to the greatest height of absurdity, and by exemplifying their emptiness and uselessness in his own person, he undoubtedly contributed more than any man to their disgrace and subsequent banishment from the science. Just as Mr Hume, by carrying the ideal system to the utmost pitch of extravagance, may be in some measure considered as the occasion of that general reform in metaphysics which has since taken place.

Van Helmont.

In 1577, or just 36 years after the death of Paracelsus, his great admirer and disciple Van Helmont was born of a noble family at Brussels. He studied medicine contrary to the inclination of his relations, was early distinguished for his extensive reading and great knowledge, and was created doctor of medicine at the age of 22, having previously read public lectures on surgery at Lovain. Soon after, happening to get a slight itch, and perceiving that the regular treatment had no effect upon it, but that sulphur speedily removed it, he became in consequence disgusted with medicine, renounced the study, divided his fortune among his relations, and left his country with an intention never more to return. He spent ten years in travelling; and at last, having acquired a knowledge of chemistry, he became violently attached to it, and resolved to devote to it the remainder of his life. In 1609, he married and returned to Wilvoord, where he employed himself in making chemical experiments, and in applying that science to medicine. His publications soon gave him celebrity, and he was more than once invited to the court of Vienna. He died in 1644, at the age of 67. Like his predecessor Paracelsus, he boasted that he was in possession of the universal remedy, to which he gave the name of *alkahest*. His chemical discoveries were numerous, and justly entitle him to distinction.

Van Helmont may be considered as the last of the alchymists. His death completed the disgrace of the universal medicine, which afterwards, like the philosophers' stone, was considered by all rational chemists as a palpable absurdity. His contemporaries, and those who immediately succeeded him, if we except Crollius and a few other blind admirers of Paracelsus, attended solely to the improvement of chemistry, and the refutation of the absurd tenets of the alchymists. The chief of them were Agricola, Beguin, Glaser, Erkern, Glauber, Kunkel, Boyle, &c.

The foundations of the alchymistical system being thus shaken, the facts which had been collected tumbled into a heap of rubbish, and chemistry was left without any fixed principles, to wander about in the dark, destitute of an object. At last, there arose a man thoroughly acquainted with the whole of these facts, capable of arranging them, and of perceiving the important purposes to which they might be applied, and able to point out the proper objects to which the researches of chemists ought to be directed.

Beccher.

This man was Beccher. He accomplished the arduous task in his work entitled *Physica Subterranea*, published at Frankfort in the year 1669. The publication of this book forms a very important era in the history of chemistry. It then escaped for ever from the trammels of alchymy, and became the science which we find it at present.

Thus it appears, that the word *chemistry* has had at different times no less than five meanings. It first signified *natural philosophy;* afterwards it was restricted to the *art of working metals;* at a later period it meant the *art of making gold;* at a still later period, the discovery of a *universal medicine* was also included under it; and, last of all, in 1669, it became the *science* which *investigates the insensible motions of bodies*. Thus, after a variety of transformations, it stopped at last, and now comprehends under it precisely one-half of its original signification. At first it was the name of the whole of natural science, whereas now it is only the name of one of the two branches into which science is divided.

John Joachim Beccher, to whom the honour of laying the foundation of the science of chemistry belongs, was born at Spires in 1625, and seems to have been of Jewish extraction. He was first a professor of medicine, then physician to the Elector of Mentz, and afterwards to the Elector of Bavaria. Towards the end of his life, he went to England, and died in London in 1682, as is suspected, in great poverty. His writings testify with what success he applied himself to the study of chemistry.

Stahl.

Ernest Stahl, his disciple, and the commentator of the *Physica Subterranea*, gave the science a degree of order and extension which raised it in some respects to a level with mechanical philosophy, and secured to himself the highest and most exalted reputation. This philosopher, a German, first physician to the King of Prussia, professor of medicine and of chemistry, who was born in the year 1660, seems to have been actuated from his very infancy by a violent passion for chemistry. At the age of fifteen he could repeat, by heart, the whole of the *Chemia Philosophica* of Barnerus, at that time the most popular book on the subject. He attached himself particularly to the writings of Beccher, whom he resembled in activity and brilliancy of imagination, and far surpassed in precision and judgment. Beccher's theory, in his hands, was new modelled and simplified. He explained the nature of combustion, and reduced the phenomena of chemistry under a certain number of general heads. His system forms as complete a whole, and has as imposing an aspect, as any which has hitherto been promulgated. It was the result of very cautious researches, and was elucidated and confirmed by satisfactory experiment. No wonder, then, that its author attracted general admiration, and that he was dignified with the title of the *sublime* Stahl. His theory consisted in supposing, that a certain substance, called *phlogiston*, forms a part of all combustible bodies; that its separation constitutes *fire*, while its various combinations produce most of the other phenomena of chemistry. It was first developed soon after the commencement of the 18th century; and Stahl's *Fundamenta Chemiæ* were first published in 1723. For a period of almost fifty years after the appearance of that book, the sole object of chemists was to confirm and extend the theory of the author. And it applied so happily to their different discoveries,—enabled them in many cases to foretel the event,—and assisted them so much to penetrate into the still unexplored recesses of nature, that we have no reason to be surprised at the admiration which it excited,—at the attachment which chemists displayed for it,—and the violence with which they supported it.

Boerhaave.

A system of chemistry, published in 1732, contributed, perhaps, as much as the theory of Stahl, though in a very different way, to the improvement and subsequent popularity of chemistry. This system was written by Boerhaave, one of the most accomplished philosophers, and perhaps the most celebrated physician that ever flourished in modern Europe. A surreptitious copy of his chemical lectures having been printed by some of his pupils, he was under the necessity, in 1732, of revising and publishing his system of chemistry: a system which contained a much fuller collection of chemical experiments, and more exact directions for repeating them, than any previously offered to the world. The bounds of the science were enlarged by this acute philosopher, who had stored his mind with the principles of mechanical philosophy. His account of fire, of thermometers, and other similar chemical instruments, was excellent, considering the period in which he wrote.

Margraaff.

Rouelle and Macquer.

The taste for chemistry which these celebrated men had inspired, together with the numerous academies and societies of different kinds all over Europe, who dedicated a portion of their time to chemical researches, occasioned numerous publications on that subject, and several discoveries of importance were the result. The science became more and more respectable, and the Stahlian theory was more completely developed, especially in Germany and in France, where several chemists of eminence successively cultivated the science. Among the German chemists, none holds a higher rank than Margraaff, a member of the Berlin Academy, to whom we are indebted for some very important discoveries. He first had the courage to call in question the authority of Stahl; and his experiments on phosphorus destroyed one of the strong holds upon which the Stahlian theory depended. Rouelle and Macquer, two Frenchmen, and associated teachers, were scarcely less celebrated; the first as a skilful practical chemist, the second as an eloquent lecturer. The first may be considered as the founder of the chemistry of animal bodies as it exists at present. When he published his analysis of urine and blood, he had scarcely any model. To Macquer, born at Paris in 1718, we are indebted for an elementary treatise on chemistry, written with such simplicity and perspicuity, that it stamped the form of subsequent works, and was even used in the different universities of Europe. We are indebted to Macquer also for a dictionary of chemistry, first published in 1766, which contributed in no common degree to the improvement of the science. In this work, the different chemical substances and instruments were described,—the theories were explained and examined,—the improvements still wanted were pointed out,—the errors and imperfections were stated with a clearness and warmth which never fail to interest the reader. This dictionary was translated into Italian, German, and English; and the translators, who were all well acquainted with the subject, rendered it still more complete by their valuable notes.

Bergman.

Chemistry was still far from being on [illegible] footing with mechanical philosophy. The reasoning employed was often loose and unsatisfactory, and frequently amounted to nothing more than far-fetched and ill-conducted analogies. The correction of these faults required all the influence of a man who had been accustomed to the rigid accuracy of mathematical demonstration,—whose profound mind had embraced every part of human knowledge,—whose sound judgment could not be biassed by prejudice,—whose industry was not to be overcome by fatigue, or want of health,—whose candour and love of truth were not to be shaken,—and who generously sacrificed himself to the improvement of the sciences. Nor need we name this philosopher. Every one who is not a total stranger to chemistry must have heard of Bergman, whose very name is a sufficient panegyric. This illustrious Swede was born in 1735, at Catherinberg, in West Gothland. His father was receiver of the revenues in that province, a post at that time neither very lucrative nor respectable, which induced him to urge his son to assume the profession of law or divinity. Young Bergman accordingly went to Upsal with that intention, and commenced his studies under the inspection of a friend. But he very soon testified a dislike to both the professions for which he was intended, while he manifested a violent passion for mathematics and philosophy. His friend remonstrated with some severity, and pointed out the imprudence of his choice. Bergman listened in silence, but still persevered in his favourite pursuits. His friend deprived him of his books, restricted his studies, and left him only to choose between law and divinity. This restraint almost proved fatal: Bergman's health declined; it was found necessary for him to leave the university, and return home. His relations, finding it in vain to struggle with his inclinations, at last indulged them, and left him at liberty to pursue those studies of which he was so distractedly fond.

At that time Linnæus, after having surmounted obstacles sufficient to have crushed a man of ordinary energy, was in the height of his glory, and was revered every where as the patriarch of natural history. He had infused the enthusiasm which actuated his own breast into the minds of his pupils, and at Upsal every student was a natural historian. Bergman, in particular, attached himself to Linnæus, and bestowed much pains on botany and entomology. This last branch of natural history is deeply indebted to him. He first displayed in it those powers of arrangement which constitute the charm of his works, and that penetration which produced afterwards such important fruits. On his return to the university, he imparted his discoveries to Linnæus, who sent them with a very flattering panegyric to the Academy of Stockholm,—"*Vidi et obstupui!*"

In the year 1761, Bergman was appointed teacher of mathematics and natural philosophy at Upsal. He was in this situation in 1767, when Wallerius, at that time professor of chemistry at Upsal, resigned his chair. Bergman offered himself as a candidate for the vacant professorship. But Wallerius had other plans. There was a relation of his own whom he wished to succeed him, and the professors at Upsal had so much influence that few doubted but he would accomplish his plan. Bergman, to shew himself qualified for the place to which he aspired, published two dissertations on alum, which were attacked by Wallerius in a style of acrimony altogether unworthy of his reputation. Gustavus IV. late king of Sweden, was at that time Prince Royal, and chancellor of the university. The character and abilities of this extraordinary man, and the zeal with which he sometimes supported men of science, are well known. Fortunately for chemistry, and for the reputation of Sweden, Gustavus took the part of Bergman, on the recommendation, it is said, of Von Swab, who pledged himself to be answerable for his qualifications; and he was so keen on the subject, that he supported his cause in person before the senate. Wallerius and his party were of course baffled, and Bergman got the chair. He filled it with the greatest glory for seventeen years; and, during that period, his numerous publications entirely altered the appearance of chemistry. He introduced an order, a perspicuity, an exactness, which were unknown before, and which were certainly one of the great causes of the subsequent rapid progress of the science. Their influence was universally felt; and, as long as Bergman lived, he stood unrivalled on the continent at the head of the science.

But it was not his publications alone which constituted his merit. His lectures were no less valuable; and many of the pupils whom he educated, contributed, in no small degree, to spread his reputation. Gahn, Hielm, Gadolin, the Elhuyarts, and many others who afterwards acquired celebrity, were educated by him. His first care, after obtaining the chair, was to collect all the different chemical substances, and their products, and to form them into a cabinet. Another cabinet contained the minerals of Sweden, arranged according to the places from which they were obtained; and a third consisted of models of the different instruments employed in chemistry and in chemical manufactures. These were designed for the instruction of his pupils, whom he encouraged and inspired with that confidence and enthusiasm which is necessary for appearing with respectability in the republic of letters. One day he was told by one of his pupils, of a young man who resided in the house of an apothecary at Upsal, and who was reproached for neglecting his duties, that he might employ the whole of his time in the study of chemistry. Bergman's curiosity was excited. He paid the young man a visit, and was astonished at the knowledge which he displayed, and the profound researches which he had undertaken, notwithstanding the poverty under which he laboured, and the restraint under which his situation placed him. He encouraged his ardour, and made him his favourite pupil and friend. This young man was Scheele, one of the most extraordinary chemists that ever existed.

Scheele.

He was born in 1742, at Stralsund, the capital of Swedish Pomerania, where his father was a tradesman. Young Scheele, at a very early period of his life, shewed a strong inclination to learn pharmacy; and was accordingly bound apprentice to Mr Bauch, an apothecary at Gottenburg, with whom he lived eight years. Here he first found the impulse of that genius which afterwards made him so conspicuous. He durst not, indeed, devote himself openly to chemical experiments, but he contrived to make himself master of the science, by devoting those hours to study which were assigned him for sleep. According to the testimony of Mr Grunberg, his fellow apprentice, he was of a very reserved and serious disposition, but uncommonly diligent. He attended very minutely to all the processes,—reflected on them while alone, especially during the night-time,—and read every thing relating to the subject in the writings of Neuman, Lemery, Kunkel, and Stahl. Kunkel's *Laboratory* was his favourite book. He used secretly, during the night-time, to repeat experiments out of it. On one of these occasions, as he was employed in making pyrophorus, another apprentice, without his knowledge, put some fulminating powder into the mixture. The consequence was a loud explosion: the whole family was thrown into confusion, and our young chemist was severely chastised.

From Gottenburg, Scheele went to Malmo, and two years after to Stockholm. In 1773 he went to Upsal, and resided for some time in the house of Mr Loock. Here Bergman first found him,—saw his merit, and encouraged it,—adopted his opinions,—defended him with zeal, and took upon himself the charge of publishing his treatises. He gave him free access to his laboratory, and procured him a salary from the Swedish Academy. Encouraged by this magnanimous conduct, the genius of Scheele, though unassisted by education or by wealth, burst forth with astonishing lustre; and, at an age when most philosophers are only rising into notice, he had completed a career of discoveries which have no parallel in the annals of chemistry. His treatises are perfect models of chemical research, and display an ingenuity, knowledge, and address, which is altogether astonishing. Nothing was capable of baffling his patient industry, or of escaping his penetrating eye.

Scheele and Bergman cannot well be compared together. Their zeal, indeed, for the science, their candour, their love of truth, and their industry, were equal; but Bergman was distinguished by the extent of his views, and by the plans which he formed for the improvement of the science; Scheele, by the skill with which he conducted particular analyses, and the acuteness with which he distinguished substances by their properties. Bergman's views were general; Scheele's were particular. Bergman was the man for drawing the outline; but Scheele understood best how to fill it up. On one occasion, indeed, (we allude to his treatise on *fire*,) he attempted a general subject, but his success was not great. However, the acuteness with which he treated it must be admired; and the vast number of important facts which he brought forward to support his opinion, are truly astonishing, and perhaps could not have been brought together by any other man than Scheele.

Chemistry was deprived of these two illustrious philosophers, Bergman and Scheele, almost at the same time. Bergman died in 1784, at the baths of Medwi, in the 49th year of his age, crowned with glory, after a life spent in the most laborious industry. Scheele was snatched away in 1786, in the 44th year of his age. For about six months previous to his death, he had been severely afflicted with the gout. When he began to perceive that his end was approaching, he was induced, from a principle of gratitude, to marry the widow of his predecessor. The ceremony was performed on the 19th of May, while Scheele lay on his death-bed. On the 21st, he left her by his will the whole of his property; and the same day on which he had so tenderly provided for her, he died. "Thus," says Dr Crell, "in less than two years, the world lost Bergman and Scheele, two men of whom Sweden, rich as she is in great and learned men, has the strongest reason to be proud; two chemists who were equally beloved and lamented by their contemporaries, and whose names will be remembered by the remotest posterity with gratitude and reverence."

Black.

Cavendish.

Priestley.

While these philosophers were employed in cultivating chemistry in Sweden, discoveries were made in Scotland which changed the apparatus and the mode of reasoning, reduced under the dominion of chemistry a number of invisible substances which had been considered formerly as too subtile for exertion, and thus occasioned a complete revolution in the science. Dr Joseph Black, from whom these discoveries originated, was born in Bourdeaux, in 1728. His father was a native of Belfast, but of a Scotch family residing in Aberdeenshire. Dr Black was educated in Belfast, and completed his education at the universities of Glasgow and Edinburgh. He discovered, after an ingenious investigation, that limestone, and the mild alkalies, are compounds of lime and pure alkalies, with an aërial fluid, to which he gave the name of *fixed air*. This discovery led to the origin of pneumatic chemistry. Mr Cavendish soon after investigated the properties of fixed air and hydrogen gas. About the year 1770, the subject was taken up by Dr Priestley, who discovered a great variety of aërial fluids, and acquired a most splendid reputation. No man, not even excepting Scheele, ever began the cultivation of chemistry under greater disadvantages than Dr Priestley, and yet few have made more numerous or more important discoveries. He was an obscure dissenting clergyman, extremely unpopular in consequence of his opinions, which involved him in almost perpetual controversy; his income was exceedingly small, yet he was loaded with a family, and obliged to spend most of the day in teaching to be able to support them. He was totally ignorant of chemistry, unprovided with any apparatus, and not in possession of the means of supplying one. These circumstances, which at first sight seemed to preclude the possibility of his entering upon the chemical career, probably when coupled with his great abilities and activity, contributed essentially to his ultimate success.

Lavoisier.

The splendid discoveries of the British chemists drew the attention of Lavoisier to the subject as early as the year 1770. He repeated and verified all their experiments of importance, together with those of the German chemists. He was early satisfied of the imperfections of the Stahlian theory, with which the new discoveries in pneumatic chemistry could not be reconciled; and after a most elaborate and ingenious investigation, persevered in for a series of years, with the utmost application, he succeeded in establishing a theory nearly the reverse of that of Stahl. For several years after he had satisfied himself of the truth of his opinions, he was not able to produce a single convert either in France or in any other country. At last, Mr Cavendish, by discovering the composition of water and of nitric acid, removed the grand objections to his opinions, and enabled him to explain his new doctrine in a satisfactory manner. Upon this Mr Berthollet declared himself a convert in 1785. His example was followed by Fourcroy; and in 1787, Morveau, during a visit to Paris, was convinced of his former mistakes, and induced to embrace the same opinions. The example of these eminent men was followed by that of all the young chemists in France. Mr Kirwan, who had acquired a great reputation by his chemical writings, had published a defence of the doctrine of phlogiston. This essay Mr Lavoisier got translated into French, and it was published, with a refutation, by some eminent chemist, at the end of each section. The refutation convinced Mr Kirwan, and induced him to embrace the Lavoisierian theory. His example was followed by Dr Black, and by almost all the eminent British chemists. Indeed, Dr Priestley was almost the only one who did not renounce the phlogistic theory.

Lavoisier and his associates, to make their victory still more certain and complete, invented a new chemical nomenclature, which they proposed, in 1787, as a substitute for the old. This nomenclature they adopted in all their writings. A violent controversy was the result, which terminated in the complete triumph of the French nomenclature in every country in Europe.

Davy.

Such is a concise view of the progress of chemistry down to our own time. Within these few years, very splendid additions have been made to the science, especially by the sagacity of Mr Davy. And at present, in consequence of the recent and unexpected galvanic discoveries, the Lavoisierian theory stands a considerable chance of being new modelled, if not in a great measure overthrown. Several important and necessary modifications have already taken place, and others not less important will probably follow.

We shall endeavour in this article to give a concise but comprehensive view of the present state of the science. From the uncertainty to which chemical theory is liable, and the improbability of ever being able to reach absolute certainty, though every new modification and improvement is probably an approximation, we cannot avoid falling into error when we attempt to theorise. To this we are particularly liable in one very important branch of the science, that namely which treats of *heat*, which is still very vague, even in its best established points. But we shall endeavour to avoid error as far as is in our power, by adhering closely to accurate experimental details, and by pointing out, as clearly as we can, what is certain, from what is still doubtful or hypothetic.

We shall divide this article into three Parts. In the first, we shall treat of the elements of the science. In the second, we shall take a chemical view of nature. In the third, we shall give a short sketch of the most important *chemical apparatus*.

PART I.

ELEMENTS OF CHEMISTRY.

Elements of Chemistry. Object.

As the object of chemistry is to ascertain the constituents of bodies, the way in which these constituents combine, and the nature of the combinations which they form, the science naturally divides itself into three parts: 1. A description of the component parts of bodies, or of *simple substances*, as they are called. 2. An account of the *compound* bodies formed by the union of the simple substances. 3. An account of the nature of the power which induces the particles of bodies to unite. This power is usually called *affinity*. These three particulars will form the subject of the three following Books.

BOOK I.

OF SIMPLE SUBSTANCES.

Simple substances.

We are probably ignorant at present of bodies, strictly speaking, elementary or simple. All that is understood in chemistry by a *simple substance*, is a substance not yet decomposed, and which we cannot shew to be a compound. Those of that kind at present known are about forty-eight. They may be divided into two classes; those which can be confined in vessels, and of course exhibited in a separate state; and those which cannot be confined in any vessels that we possess, and the existence of which is only inferred from certain phenomena exhibited by the first class of bodies in certain circumstances. The first class of bodies may be called *confinable*, the second *unconfinable*.

DIVISION I.

Of Confinable Bodies.

Confinable bodies.

The confinable bodies may be arranged under the four following heads:

1. Simple supporters of combustion.
2. Simple combustibles.
3. Simple incombustibles.
4. Metals.

These classes shall be treated of in order in the four following Chapters.

Chap. I.

Of Simple Supporters of Combustion.

Simple supporters of combustion.

The term, *supporter of combustion*, is applied to those substances which must be present before combustible substances will burn. Thus *air* is a supporter of combustion, because a candle will not burn unless it be supplied with air. All supporters, not yet decompounded, are called *simple*.

Elements of Chemistry.

We are at present acquainted with two simple supporters of combustion, namely, *oxygen* and *chlorine*.

Sect. I. *Of Oxygen.*

Oxygen.

This substance is an *air*, or, as chemists use to call aërial bodies, a *gas*.* It was discovered by Dr Priestley, on the 1st of August 1774. It may be obtained by heating *black oxide of manganese* in an iron bottle fitted with a long iron tube. The extremity of the tube is plunged into a trough of water, having a shelf a little below the surface, on which stands an inverted glass cylinder full of water. The open mouth of this cylinder is brought over the extremity of the iron tube. As soon as the manganese is red hot, air issues from the extremity of the tube, and gradually fills the glass vessel, displacing the water. In this way any quantity of oxygen gas may be procured. Red lead, or red precipitate, may be substituted for the manganese, but they do not yield so much oxygen. The salt called hyperoxymuriate of potash may also be used, and it yields a very great proportion of pure oxygen. Oxygen gas may also be obtained, by putting the manganese in powder into a glass retort, and pouring on it as much *sulphuric acid* as will make it into a thin paste. The heat of a lamp being applied to the retort while its beak is plunged into the water trough, the gas is disengaged in considerable quantity.

How procured.

This gas was called by its discoverer *dephlogisticated air*; Scheele, who likewise discovered it, called it *empyrial air*; Condorcet gave it the name of *vital air*; and at last Lavoisier, from an hypothesis respecting the formation of acids, distinguished it by the appellation of *oxygen gas*, which it now bears.

Its properties.

Oxygen gas possesses the mechanical properties of common air. It is colourless, invisible, and capable of indefinite expansion and compression.

Combustibles burn in it better and brighter than in common air. Animals can breathe it longer than common air without suffocation.

It has been ascertained, that one-fifth of the air of the atmosphere is oxygen gas, and that when this portion is abstracted, the air can neither support combustion nor animal life.

When substances are burnt in oxygen gas or air, or when animals breathe them, a portion of the oxygen always disappears, and, in some cases, even the whole of it.

---

* The term *gas* is applied by chemists to all *airs* except *common air*.

Its specific gravity, according to Kirwan, is 1.103; according to Davy, 1.127; according to Fourcroy, Vauquelin, and Seguin, 1.087; according to Saussure, junior, 1.114, that of air being 1.000. At the temperature of 60°, and when the barometer stands at 30 inches, 100 cubic inches of common air weigh very nearly 30.5 grains troy. 100 cubic inches of oxygen in the same temperature and pressure, weigh, according to these results, 33. grains, 34.37 grains, 33.15 grains, and 33.97 grains troy.

It is not sensibly absorbed by water. 100 cubic inches of water freed from air by boiling, absorb 3.55 inches of this gas, according to the experiments of Dr Henry.

Oxygen is capable of combining with a great number of bodies, or it has an *affinity* for them, and forms compounds with them.

Sect. II. *Of Chlorine.*

Chlorine.

This substance was first discovered by Scheele, and called by him *dephlogisticated muriatic acid.* Berthollet, who made many important experiments on it, and who conceived it to be a compound of muriatic acid and oxygen, gave it the name of *oxymuriatic acid.* Mr Davy has lately made it the subject of investigation, and has published some very important dissertations on it. He has shewn, by decisive experiments, that we have no proof of its containing oxygen. This has induced him to revive the original opinion of Scheele respecting its nature, and convinced of the impropriety of the old names by which it was distinguished, and aware of the hazard of giving it a name from theoretical considerations, he has contrived the term *chlorine*, derived from the green colour, by which it may be distinguished from all other gaseous bodies.

How procured.

Chlorine may be obtained by distilling a mixture of muriatic acid and the black oxide of manganese; or by mixing together three parts of common salt, and two parts of black oxide of manganese in a glass retort, and pouring over them two parts of diluted sulphuric acid. When this mixture is heated, a green coloured gas makes its appearance, which may be collected in glass phials over water. This gas is the substance in question.

Its properties.

This gas has a yellowish green colour, its odour is extremely offensive and suffocating, and it cannot be breathed. When drawn into the lungs mixed with common air, it occasions a violent cough, which lasts for some time, accompanied with a sense of oppression and of weakness. It is capable of supporting combustion. Indeed, many substances, as phosphorus, antimony, &c. take fire in it of their own accord, without being kindled. Its specific gravity is 2.713, that of air being 1.000.

It is not altered by exposure to light, or to a red heat.

Water absorbs it slowly, and acquires a green colour, and the smell and properties of the gas. It may be frozen without losing the gas, but it is easily extricated by heat. When this liquid is exposed to the light, the chlorine disappears, oxygen gas escapes, and a portion of muriatic acid is found dissolved in the water.

Chlorine has the property of destroying vegetable blues, and other vegetable colours. This property has rendered it a valuable article in bleaching.

Euchloric gas.

Oxygen has the property of combining with chlorine, and of forming with it a peculiar yellow-coloured gas, hitherto not much examined. It was discovered by Mr Davy. To obtain it, the salt formed by passing a current of chlorine through a solution of carbonate of potash, a salt formerly distinguished by the name of hyper-oxymuriate of potash, is put into a flask, and diluted muriatic acid poured upon it. An effervescence takes place; and, by the cautious application of a very moderate heat, the combination in question comes over. Mr Davy proposes to distinguish this new gas by the name of euchloric gas, in consequence of the great intensity of its colour. Combustible substances do not act upon this gas so powerfully as upon chlorine. Indeed, the metals do not act upon it at all till it is decomposed. When exposed to a moderate heat, it is decomposed, and the expansion is accompanied by an explosion.

As far as we know at present, chlorine, like oxygen, is a simple substance; and it is, in some respects, a more powerful supporter of combustion than oxygen itself.

Like oxygen, it has an affinity for a great number of bodies, and forms peculiar compounds by uniting with them.

Chap. II.

Of Simple Combustibles.

Simple combustibles.

By *combustible* is understood a substance capable of burning; and by *simple combustibles*, bodies of that nature not yet decomposed. They are five in number, namely, *hydrogen, carbon, phosphorus, sulphur*, and *boracium.* It is not impossible that the bases of all or most of these substances are metals; but the opinion has not yet been made out in a satisfactory manner.

Sect. I. *Of Hydrogen.*

Hydrogen.

Hydrogen, like oxygen, is a gas. It was first called *inflammable air*, and Mr Cavendish must be considered as its real discoverer.

How procured.

It may be procured by putting some clean iron or zinc filings into a glass retort, and pouring over them sulphuric acid diluted with thrice its bulk of water. A violent boiling takes place, or, as chemists term it, an *effervescence*; gas issues abundantly from the beak of the retort, and may be received like the oxygen in glass vessels standing in a trough of water.

Its properties.

It is invisible and colourless, and possesses the mechanical properties of common air.

When prepared by the above process, it has a peculiar smell, ascribed at present to the presence of a little *oil*, formed by the action of the acid on the iron filings.

It is the lightest gaseous body known. Its specific gravity, according to Kirwan, is 0.0843; according to Lavoisier, 0.0756; according to Fourcroy, Vauquelin, and Seguin, 0.0887; according to Davy, 0.0744. According to these various estimates, 100 cubic inches under the mean pressure and temperature, weigh 2.56 grains, 2.306 grains, 2.705 grains, and 2.27 grains Troy. It is about 13 times lighter than common air.

No combustible substance will burn in it; and no animal can breathe it for any length of time without death.

Forms water,

It burns when touched with a red hot iron, or when brought near a flaming taper. The colour of the flame is yellowish, and it gives but little light. If it be previously mixed with half its bulk of oxygen gas, it burns instantaneously, and with a loud explosion like the report of a pistol. If the mixture be put into a strong glass cylinder, standing over water, and kindled by an electric spark, the whole of the two gases disappears, and the cylinder is filled with the water. If the vessel be standing over mercury, or be hermetically sealed, its inner surface becomes coated with pure water. This water was found by Cavendish equal in weight to the two gases. Hence it has been inferred, that water is a compound of oxygen and hydrogen in the proportion of 7.5 by weight of oxygen to 1 of hydrogen.

and muriatic acid.

When equal bulks of hydrogen and chlorine are mixed together in a glass vessel, no change takes place in the dark; but if the vessel be exposed to the sun, the mixture burns with an explosion. It burns also if an electric spark be passed through it. In both cases, the two gases disappear entirely; and there is found in their place a quantity of muriatic acid gas almost exactly equal to them in bulk. Now, the specific gravity of muriatic acid gas is almost exactly the mean of that of hydrogen and chlorine.—Hence the weight does not change sensibly. From this experiment it is inferred, that muriatic acid gas is a compound of chlorine and hydrogen, in the proportion of equal bulks of each in the gaseous state, or by weight of 97.24 chlorine
2.76 hydrogen

100.00

Hydrogen is not sensibly altered or absorbed by water. 100 cubic inches of water deprived of air absorb 1.53 inches of hydrogen, according to the experiments of Dr Henry.

Sect. II. *Of Carbon and Diamond.*

Carbon and diamond.

If a piece of wood be heated to redness in an iron bottle, or a crucible filled with sand, it is converted into a black brittle substance called *charcoal;* the properties of which are nearly the same from what wood soever it has been obtained, provided it has been exposed to a sufficiently strong heat.

Charcoal.

Charcoal is insoluble in water, and not affected (provided air be excluded) by the most violent heat that can be applied.

It conducts electricity, is not liable to putrify, deprives meat of its putrid taste and smell, and is an excellent tooth powder.

It absorbs moisture with avidity, and likewise common air, oxygen, and hydrogen gas; but less of the last than of the two former.

When heated to 802°, it takes fire; and, if pure, burns all away without leaving any residuum. If the experiment be made in a glass vessel filled with oxygen gas, and the charcoal be heated by means of a burning-glass, the bulk of the oxygen gas is not altered, but a portion of it is converted into another gas, possessing quite different properties. It renders lime-water milky, and is quite absorbed by it, and cannot be breathed without occasioning instant death. This gas is called *carbonic acid.* It very nearly equals in weight the charcoal and the oxygen which have disappeared. Hence it is considered as a compound of them; and, from the proportion of each employed, it is considered as composed of very nearly 28 parts of charcoal, and 72 of oxygen.

Forms carbonic acid.

When considerable quantities of charcoal are burnt in this manner, a portion of water also appears. Hence it is conceived, that charcoal contains a small portion of hydrogen. The constituent which constitutes by far the greatest part of it, is called *carbon.* This supposition is corroborated by the late experiments of Mr Davy. Carbon exists in two other states, namely, the diamond and plumbago.

Diamond.

2. The diamond is a precious stone, transparent, and often crystallized in a six-sided prism, terminated by six-sided pyramids. It is the hardest of all bodies. Its specific gravity is about 2.3. It is a non-conductor of electricity.

When heated to the temperature of 14° of Wedgewood's pyrometer, or not so high as the melting point of silver, it gradually wastes away and burns. It combines with nearly the same quantity of oxygen, and forms the same proportion of carbonic acid as charcoal. Hence it consists chiefly of carbon. From the experiments of Davy, it has been inferred, that it contains a minute portion of oxygen as one of its constituents. The other constituent is carbon.

Plumbago.

3. Plumbago, called also *black lead* and *graphite,* is well known as the substance of which pencils are made. It is dug out of the earth; it is of a dark blue colour, and has some metallic lustre; it is soft, brittle, and infusible. When heated to redness, it gradually wastes away, and is converted into carbonic acid, leaving a little iron behind. It seems a compound of pure carbon, with about one twentieth part of its weight of iron.

Neither charcoal, diamond, nor plumbago, provided they be pure, are affected by chlorine. They do not combine with it, and may be heated in it to whiteness, without undergoing any alteration.

Carbon combines with hydrogen, and forms a gas formerly called heavy *inflammable air,* now carbureted hydrogen. Various gases were formerly called *heavy inflammable air.* The three following are the chief:

Carbureted hydrogen.

1. *Carbureted hydrogen.* It rises spontaneously in hot weather from stagnant water; it is evolved during the distillation of pitcoal; it is invisible, and possesses the mechanical properties of common air. Its specific gravity is 0.5554. One hundred cubic inches weigh 16.93 grains. For complete combustion, it requires twice its weight of oxygen. The products are its own bulk of carbonic acid and wa-

ter. Hence its constituents are carbon and hydrogen. The following are nearly the proportions:

28 hydrogen
72 oxygen
———
100

The gas obtained from pit-coal by distillation, consists chiefly of this gas.

Carbureted hydrogen gas burns with a yellow flame, and gives out a great deal of light.

Olefiant gas.

2. When four parts of sulphuric acid, and one part of alcohol, are heated in a retort, a gas comes over called *olefiant gas*, or *super-carbureted hydrogen*. It is invisible; has a disagreeable smell; its specific gravity is 0.9745. It burns with a dense white flame, and great splendour, and requires thrice its bulk of oxygen for complete combustion. The products are water and twice its bulk of carbonic acid. Hence it has been concluded, that this gas is composed of

85 carbon
15 hydrogen
———
100

When this gas is mixed with chlorine over water, the bulk of the mixture diminishes rapidly; and an opal coloured substance, like oil, swims upon the surface of the liquid. This substance seems to be a compound of the two gases. It dissolves in water, alcohol, and ether, and gives these liquids a hot and aromatic taste. It dissolves likewise in nitric acid without effervescence; but in sulphuric acid it effervesces, and chlorine is emitted.

Carbonic oxide.

3. *Carbonic oxide*. When a mixture of equal parts of iron filings and dry chalk is heated to redness in an iron retort, a gas comes over, partly carbonic acid and partly carbonic oxide. The former is washed away by means of lime water.

Carbonic oxide gas is invisible; its specific gravity is 0.956. It burns with a deep blue flame, and gives out but little light. For complete combustion, 100 measures of it require 40 of oxygen gas. The product is 92 measures of carbonic acid. As the carbonic acid produced is almost equal to the weight of the carbonic oxide and oxygen consumed, it is presumed that there is no other product. Hence carbonic oxide is considered as a compound of carbon and oxygen in the following proportions:

39 carbon
61 oxygen
———
100

Phosgen gas.

When equal bulks of this gas and chlorine gas are exposed to a strong light over mercury, they combine and form a gas just half the bulk of the constituents. It possesses acid properties. Water decomposes it; and muriatic acid and carbonic acid are obtained. This curious gas was discovered by Mr John Davy. Its specific gravity is 3.669; and 100 cubic inches of it weigh, under the mean pressure and temperature, 111.91 grains. It combines with four times its bulk of ammoniacal gas, and forms a neutral salt. Alcohol absorbs about 12 times its bulk of this gas without decomposing it. Mr John Davy has given this remarkable compound the name of *phosgen* gas, because it is formed by the action of light or its two constituents.

Sect. III. *Of Phosphorus.*

Phosphorus.

How procured.

Phosphorus may be obtained by pouring acetate of lead into urine, mixing the white powder which precipitates with charcoal, and distilling it in an earthen retort by means of a violent heat. The beak of the retort ought be plunged under water. The phosphorus drops into the water like melted wax. It is usually obtained from burnt bones.

It was discovered in 1669, by Brandt, a chemist of Hamburgh; afterwards by Kunkel; and last of all by Boyle, who taught his operator, Godfrey Hankwitz, to make it; and he for several years was the only person that could make it.

Its properties.

Phosphorus, when pure, is semitransparent and yellowish, but when kept in water it becomes white and opake, and has some resemblance to white wax. It is soft, and may be easily cut with a knife. It is insoluble in water. Its specific gravity is 1.770.

It melts at the temperature of 99°. It cannot easily be melted in the open air without taking fire. If air be excluded, it evaporates at 219°, and boils at 554°.

When exposed to the air, it emits a white smoke with the smell of garlic, and is luminous in the dark. This smoke is more abundant the higher the temperature, and is occasioned by the gradual combustion of the phosphorus. In oxygen gas it is not luminous unless the temperature be as high as 80°. Hence we learn, that it burns at a lower temperature in common air than in oxygen gas. This slow combustion in the open air, renders it necessary to keep phosphorus in phials filled with water and well corked.

Phosphoric acid.

When heated to 148°, it takes fire and burns with a vivid white flame, and emitting a vast quantity of smoke. It leaves (if pure) no residuum, but the white smoke when collected is an *acid*, and is called *phosphoric acid*. If the combustion be conducted in a jar filled with oxygen gas, the oxygen will be found to diminish so much, that every 100 parts of phosphorus occasion the disappearing of 114 parts of oxygen. The acid formed weighs as much as the phosphorus and the oxygen which have disappeared. Hence it is considered as a compound of these two, in the proportion of 100 parts of phosphorus to 114 of oxygen.

Oxide of phosphorus.

Phosphorus is supposed capable of combining with a small portion of oxygen, and of forming a compound called *oxide of phosphorus*. It may be formed by putting a bit of phosphorus in a long glass tube, and exposing it to the heat of boiling water. It *sublimes* and lines the tube in fine white flakes. This substance is very combustible, and often takes fire of its own accord when exposed to the air.

When introduced into chlorine, phosphorus burns with a clear bluish white flame, and is converted into a solid white matter, which seems to consist of the two substances united. When this compound is placed in contact with water, it is converted into phosphoric acid and muriatic acid.

When phosphorus is melted by means of a burning

Phosphureted hydrogen.

glass in hydrogen gas, a portion of it is dissolved, and a new gas formed, first discovered by Gemgembre, and called *phosphureted hydrogen gas.* It has a fetid odour like the smell of putrid fish. It burns spontaneously, when it comes into contact with common air or oxygen gas. Water dissolves a small portion of this gas, and acquires a bitter taste and unpleasant odour. The phosphorus gradually precipitates, and the hydrogen at the same time separates from the water. When kept in a glass jar, it soon loses its property of burning spontaneously.

From the experiments of Mr Davy, we learn, that when hydrogen gas is converted into phosphureted hydrogen, its bulk does not alter; and from the experiments of Mr Dalton, it follows, that the weight of 100 cubic inches of it under the common pressure, and at the temperature of 60°, is 26 grains. From these data, it is easy to establish its composition. Its constituents are obviously,

phosphorus	91.23
hydrogen	8.77
	100.00

Phosphorus combines with charcoal, and forms a compound of an orange red colour, called phosphuret of carbon. Common phosphorus contains a portion of this compound, which remains behind when the phosphorus is burnt. It is a light flocky powder, without taste or smell. When heated sufficiently, it burns, and the charcoal remains behind.

The compounds which phosphorus forms with the other bodies, are distinguished by the name of *phosphurets.*

Phosphorus is very poisonous when used internally. It has been recommended as a medicine, and said to be very efficacious in restoring the force of young persons exhausted by sensual indulgence.

Sect. IV. *Of Sulphur.*

Sulphur.

Sulphur, distinguished also by the name of *brimstone,* has been known since the earliest ages.

Its properties.

It is a hard brittle substance, of a greenish yellow colour, without any smell, and with very little taste. It is a nonconductor of electricity, and becomes electric *negatively* by friction. Its specific gravity is 1.990. It is not altered by exposure to the air, nor is it soluble in water.

When heated to 170° it rises up in the form of a fine powder, which may be easily collected, and is called *flowers of sulphur.* It is then said to be *volatilized* or *sublimed.* It is obvious, from this property, that sulphur is a volatile substance.

Sulphuric acid.

When heated to about 218° it melts, becomes transparent, and looks like a brown coloured oil. At 560° it boils, and the vapour kindles as it exhales, and burns with a blue flame, and an extremely disagreeable smell. If it be set on fire, and plunged into a jar filled with oxygen gas, it burns with a strong violet flame. In both cases (provided the quantity of air or oxygen be sufficient) it burns away completely without leaving any residue. But if the fumes be collected, they are found to be an acid, which is known by the name of *sulphuric acid.* A portion of the oxygen disappears; and, from the experiments of Lavoisier, it follows, that the sulphuric acid formed is exactly equal in weight to the sulphur and the oxygen which have disappeared during the combustion. Hence it is concluded, that this acid is composed of these two substances united together.

Many experiments have been made to ascertain the composition of sulphuric acid exactly. The following is the result which appears most accurate. It was obtained by Berzelius.

100	sulphur
150	oxygen
250	

Sulphurous acid.

But sulphur does not always combine with so great a portion of oxygen. It usually burns with a blue flame, and the suffocating vapours which it emits may be collected in glass cylinders filled with mercury, and standing in a trough containing mercury. They constitute a gas called *sulphurous acid.* It contains less oxygen than sulphuric acid, being compounded of

100	sulphur
100	oxygen
200	

When sulphur is kept melted in an open crucible, it becomes gradually thick and viscid. If it be now poured into water, it assumes a purple colour, and remains for some days soft; but it gradually becomes brittle, and of a light violet colour. Its texture is fibrous, and its specific gravity 2.325. In this state it has been called *oxide of sulphur,* from an opinion that it has combined with a little oxygen, and that this addition has altered its properties. But this opinion has not been proved experimentally.

Lac sulphuris.

When sulphur is dissolved in any liquid, as in a solution of potash, and then precipitated by an acid, it is always in the state of a white powder, known by the name of *lac sulphuris.* This powder consists of sulphur combined with a little water. When the water is driven off by heat, the white colour of the sulphur disappears, and its natural yellow colour returns.

When a current of chlorine is made to pass through a quantity of flowers of sulphur, or when sulphur is heated in chlorine, it gradually disappears, and a beautiful red liquid appears in its place. Its specific gravity is 1.623. It smokes very strongly, has a strong smell, and is very volatile. It dissolves phosphorus readily. When mixed with water, it is decomposed, and a quantity of sulphur separates. This substance is obviously a compound of sulphur and chlorine. Water decomposes it; and, in that case, sulphuric and muriatic acids are formed.

Sulphureted hydrogen.

Sulphur combines readily with hydrogen gas, and forms a gas known by the name of *sulphureted hydrogen,* which was first described by Scheele.

It may be formed by mixing together *potash* and sulphur, and boiling them together in a glass flask. When sulphuric acid is poured into the yellowish coloured liquid that is formed, an effervescence takes place, and the gas may be collected in proper vessels. It is obtained pure by digesting sulphuret of antimony in muriatic acid.

Sulphureted hydrogen gas is colourless, and possesses the mechanical properties of common air. It has a strong fetid smell, like that of rotten eggs. It neither supports combustion, nor animal life. Its specific gravity, according to Kirwan, is 1.106; according to Thenard, 1.231; according to Davy, 1.147. Water absorbs about its own weight of this gas, and acquires a fetid smell, a sweetish nauseous taste, and many of the properties peculiar to acids.

When this gas is set on fire, it burns with a reddish blue colour, and deposits a quantity of sulphur. When the electric spark is passed through it, sulphur is deposited, but the bulk of the gas is not altered. Sulphur is also deposited when *nitric acid* is dropt into water impregnated with it. When mixed with oxygen gas, and burnt, the only substances formed are sulphuric acid and water. Hence it is obvious, that its constituents are sulphur and hydrogen.

From the experiments of Mr Davy we learn, that when sulphur is heated in hydrogen gas, a portion of sulphureted hydrogen is formed, but the bulk of the gas is not altered. Hence the specific gravity of the gas obviously gives us the proportion of its constituents. It must consist of

Sulphur	93.5
Hydrogen	6.5
	100.0

Supersulphureted hydrogen. Sulphur acts upon charcoal at a red heat. If a quantity of charcoal be put into a porcelain tube, and heated to redness, by passing it through a furnace, and sulphur be made to pass through it while in that state without any communication with the external air, a substance issues from the extremity of the tube, which may be obtained by means of a crooked glass tube luted to the porcelain tube, and plunged to the bottom of a glass vessel filled with water. This substance is a liquid, colourless and transparent when pure, but often tinged greenish yellow. Its taste is cooling and pungent, and its odour strong and peculiar. It does not dissolve in water. Its specific gravity is 1.3. In an exhausted receiver, or at the top of a barometrical tube, it assumes the gaseous form. It burns very easily, and detonates when mixed with oxygen gas and kindled. It was first discovered by Lampadius, and Clement and Desormes; and Berthollet, junior, investigated its properties. It is composed of sulphur and hydrogen, but contains more sulphur than sulphureted hydrogen. It may therefore be called *super-sulphureted hydrogen*.

Phosphuret of sulphur. Sulphur and phosphorus readily combine, and in various proportions; but the compound seems to be most intimate when the weights of the two ingredients are equal. The combinations may be made by mixing the two ingredients in a small phial and melting them together, or by cautiously heating them in a flask filled with water. But the first method is less hazardous; for the compound acts upon the water, and gases are formed, which sometimes occasion violent explosions. The compound has a yellowish green colour: it may be distilled over in a glass retort without decomposition. It has a tendency to the liquid form, which is greatest when equal proportions of the constituents are used. It then remains liquid in the temperature of 41°. When the sulphur predominates in this compound, it may be called *phosphuret of sulphur*; when the phosphorus, *sulphuret of phosphorus*. It is very combustible, and often takes fire spontaneously when exposed to the air.

From the experiments of Clayfield and Berthollet, junior, there is reason to conclude that sulphur contains a small quantity of hydrogen.

Sect. V. *Of Boracium.*

Boracium. This substance was discovered by Mr Davy, but it was first described by Thenard and Gay-Lussac. Mr Davy has lately published a more detailed account of its properties. How procured. To procure it, equal weights of the metal called *potassium* and dry *boracic acid* are to be put into a copper tube, and exposed for some minutes to a slight red heat. When cold, the mass is to be washed out with water, the potash saturated with muriatic acid, and the whole thrown upon a filter. An olive-coloured matter remains, which must be washed and dried. It is *boracium*.*

Its properties. Boracium is of a dark olive colour, opake, brittle, its powder does not scratch glass, it is a non-conductor of electricity, and has some resemblance to charcoal. When heated to whiteness in a metallic vessel, it remains unaltered, provided common air or oxygen be excluded. After this process it sinks in strong sulphuric acid; but in its ordinary state it swims upon that liquid.

Boracic acid. When heated in common air or oxygen gas, to a temperature not quite so high as 600°, it takes fire and burns with considerable brilliancy, somewhat like charcoal, and is converted into boracic acid. By this process, a portion of the oxygen disappears. Hence boracic acid is considered as a compound of boracium and oxygen. The exact proportion of the constituents of this acid have not yet been ascertained. According to Mr Davy's experiments, it is composed of one part boracium, and two parts oxygen; while Thenard and Gay-Lussac consider it as a compound of two parts boracium and one of oxygen.

When placed in contact with chlorine, it burns spontaneously with a white light, and is partly converted into boracic acid, partly into a black matter which is considered as an *oxide of boracium*. It burns when slightly heated, and is converted into boracic acid. It decomposes sulphuric and nitric acids with the assistance of heat, and is converted into boracic acid. When melted with sulphur and kept long in contact with it, a kind of combination takes place as the sulphur acquires an olive colour. It does not combine with phosphorus. Whether it combines with hydrogen and with charcoal, has not been tried.

Potash and soda dissolve it both when liquid and when melted with it in a crucible, forming pale olive compounds, which give dark-coloured precipitates when treated with muriatic acid. It did not combine with mercury by heat.

Mr Davy has rendered it probable that it contains a little oxygen, and that, when deprived of this principle, it combines with metals, and forms compounds capable of conducting electricity.

---

* The French chemists have called it *bore*. *Boron* would be a better name than either.

Properties of the simple combustibles.

Such are the properties of the simple combustible bodies; none of which, unless hydrogen be an exception, are, strictly speaking, simple substances, though we are not in possession of any accurate method of separating their constituents, and exhibiting them in a separate state. It is very likely that the hydrogen and oxygen separated from several of them, may be owing to the presence of water in them, from which it is very difficult to separate them completely.

Two of them, *boracium* and *carbon*, are solids which we are incapable of melting or altering by heat; two of them, sulphur and phosphorus, easily melt, and may be exhibited in a solid, liquid, or even gaseous state; while one of them, hydrogen, is always, when pure, in the state of a gas.

They all combine with oxygen, but in different proportions, as is obvious from the following table, exhibiting the quantity of oxygen capable of combining with 100 parts of each.

100 Hydrogen unites with	750 oxygen.
100 Carbon	251.6
100 Boracium	200
100 Sulphur	150
100 Phosphorus	114

It has been supposed by some, that the affinity of different bodies for oxygen, is proportioned to the quantity of it with which they combine. According to this notion, the affinity of the simple combustibles for oxygen is in the order of the preceding table.

Chlorine has the property of combining with all the simple combustibles except carbon. With hydrogen it forms muriatic acid; with sulphur, phosphorus, and boracium, it forms compounds not yet distinguished by specific names.

Hydrogen unites with all the simple combustibles, unless boracium be an exception. It is probable that they are all capable of combining with each other, at least, in one proportion, and some are known to combine in several. Chemists have agreed to give such compounds a name derived from one of the ingredients and ending in *uret*, as *sulphuret of phosphorus*, *phosphuret of carbon*. When the compound is gaseous, the term is converted into an adjective, as *sulphureted hydrogen gas, carbureted hydrogen gas.*

CHAP. III.

Of Simple Incombustibles.

Simple incombustibles.

By simple incombustibles are meant all substances incapable of combustion which have not yet been decompounded. We are acquainted with only one body of that nature at present, namely, *azote.* There can be little doubt that it is a compound, though all attempts at a regular analysis of it hitherto failed.

SECT. I. *Of Azote.*

Azote.

1. Azote, called also *nitrogen*, which was first particularly pointed out by Dr Rutherford in 1772, constitutes four-fifths of the atmosphere. The other fifth is oxygen. To obtain it pure, we have only to deprive any portion of air of the whole of its oxygen. This is easily done by confining in it for some time a mixture of sulphur and iron filings made up into a paste, or a quantity of phosphorus.

How obtained.

Dr Priestley, who was one of the original experimenters on this substance, gave it the name of *phlogisticated air*. The French chemists called it at first *mofete*, and afterwards *azotic gas*, because animals cannot breath it without death. The name *azote*, though it has prevailed, is without doubt ill chosen.

Its properties.

Azotic gas is invisible, and possesses the mechanical properties of common air. Its specific gravity, according to Kirwan, is 0.985; according to Lavoisier, 0.978; according to Biot and Arago, 0.969; that of common air being 1.000.

It neither supports flame nor animal life. Water does not sensibly absorb it. 100 cubic inches of water, freed from air by boiling, absorb about 1½ inches of this gas.

2. Though incombustible, it is capable of combining with oxygen gas. When electric sparks are passed through a mixture of oxygen and azotic gases for some time, the bulk of the mixture diminishes, and an acid is formed. If the gases be mixed in the proper proportions, they disappear entirely, and are of course totally converted into an acid. This acid is the *nitrous*. Hence it follows, that nitrous acid is composed of oxygen and azote. This important discovery was made by Mr Cavendish. The result of his experiments gives us nitrous acid composed very nearly of 30 azote,
70 oxygen.

100

or one part azote united to 2⅓ of oxygen.

Nitrous acid.

Nitrous gas.

Nitric acid is a yellow corrosive liquid, of great importance in chemistry. It acts with great energy on most other bodies, in consequence of the facility with which it parts with its oxygen. If copper or silver, for example, be put into it, the metals absorb oxygen and dissolve. The portion of acid which loses a part of its oxygen, assumes the gaseous form, and makes its escape out of the liquid, occasioning an effervescence. The gas which escapes is a compound of azote, and a smaller proportion of oxygen than exists in nitric acid. It is usually called *nitrous gas.* It has the curious property of combining with oxygen gas whenever it comes in contact with it, and of thus being again converted into nitric acid. The mixture becomes yellow; and, if standing over water, its bulk diminishes very much, because the water absorbs the acid as it forms.

Gaseous oxide.

If iron filings be kept for some days in a jar of nitrous gas, its bulk diminishes, and it loses the property of becoming yellow when mixed with common air. Its properties are now changed, and it is called *gaseous oxide of azote.* This new gas is composed of the same constituents as the former, but it contains a smaller proportion of oxygen. It supports combustion, and bodies burn in it almost with as much splendour as in oxygen gas.

Thus it appears, that azote has the property of combining with three different doses of oxygen.

3. As far as we know at present, chlorine has not the property of combining with azote.

4. The combinations of azote with the simple substances are not numerous, but some of them are important.

Ammonia.

When putrid urine, wool, and many other animal substances, are distilled, among other products, there is obtained a substance of a pungent odour and taste, known by the names of *hartshorn*, *volatile alkali*, *ammonia*. It may be obtained pure, by heating a mixture of three parts of quicklime and one part of the salt called *sal ammoniac*, in a glass flask, and receiving the product over mercury. It is a gas. When electric sparks are passed through it, its bulk is doubled, and it is converted into a mixture of azotic and hydrogen gases. Hence it is a compound of these two substances. It consists of three parts by measure of hydrogen gas, and one part of azotic gas.

Azotic gas is said to have the property of dissolving a little charcoal, which it again deposites when allowed to stand over water.

It dissolves likewise a little phosphorus, and increases about one-fortieth part in bulk. When this phosphureted azotic gas is mixed with oxygen gas, it becomes luminous, in consequence of the combustion of the dissolved phosphorus.

Azotic gas is said likewise to dissolve a little sulphur when assisted by heat. Sulphureted azotic gas is said to resemble sulphureted hydrogen gas in its properties.

Chap. IV.

Of Metals.

Metals.

Metals, one of the most important classes of bodies, and to which we are indebted for most of our improvements, are very numerous. Indeed, the present state of chemical analysis leads to the opinion that all bodies will ultimately divide themselves into two sets; namely, *metals*, and supporters of combustion.

Properties.

1. Metals are distinguished by a peculiar lustre, well known by the name of the *metallic lustre*. They are perfectly opake or impervious to light, even in the thinnest plates to which they can be reduced. The only exception is gold leaf. Its thickness does not exceed $\frac{1}{180000}$th part of an inch, and it allows the light to pass through it. If other metals could be reduced as thin, it is probable that they also would be pervious to light. They may all be melted when heated sufficiently. Some, as mercury, require very little heat to melt them; while others, as platinum, require a great deal. Their specific gravity is exceedingly various. All the old metals are at least five times heavier than water; and some, as platinum, more than twenty times heavier. But some of the new metals discovered by Davy are much lighter than water. They are the best conductors of electricity of all known bodies. None of them is very hard; but some of them may be hardened artificially, so as to exceed most other bodies. Their elasticity may likewise, in some cases, be artificially increased. Some of them are *malleable*, or may be extended by the blows of a hammer, while others are *brittle*. Some of them are *ductile*, or may be drawn out into wire, while others cannot. They differ considerably from each other in their *tenacity*, or in the weight which they are capable of supporting without breaking.

Combine with oxygen,

2. Several of them take fire when heated, and burn with considerable splendour, and almost all of them may be burnt by peculiar contrivances. After combustion, their appearance is totally changed: They have lost the metallic lustre, and are converted into earthy-like powders, formerly called *calces*, and now *oxides*. These oxides are of various colours, white, red, yellow, blue, &c. according to the metal, and several of them are employed as paints. Most metals are converted into oxides, merely by exposing them for a sufficient length of time to the action of heat and air, and all by the action of acids.

When these oxides are mixed with charcoal powder, and heated, they lose their earthy-like appearance, and are restored again to the metallic state. This process is called *reduction*. Some metallic oxides, as those of gold and silver, require only to be heated in order to be *reduced;* but most of them require also the presence of charcoal, or of some other combustible substance. These oxides were at first considered as simple substances, and the metals were supposed to be composed of them and the principle of inflammability, called phlogiston. But it was shewn by the experiments of Lavoisier, that the oxides are compounds, and that they are composed of the metals from which they were obtained, united to oxygen. Thus, *oxide of gold* is a compound of gold and oxygen. It was the discovery of this fact that induced chemists to substitute the word *oxide* for calx.

Most metals are capable of combining with various doses of oxygen, and of forming various oxides, which it is of consequence to be able to distinguish. This may be done by prefixing to the term oxide the Greek ordinal numeral, expressing the peculiar oxide. Thus, *protoxide of tin* is the first oxide of tin, or tin combined with a minimum of oxygen. *Deutoxide of tin* is the second oxide of tin, or tin combined with two doses of oxygen. The terms *tritoxide, tetroxide, pentoxide*, &c. are to be understood in the same way. The last oxide of a metal is called *Peroxide*. *Peroxide* means a metal combined with as much oxygen as it can take up, or a metal saturated with oxygen.

and with combustibles.

3. Metals combine with the simple combustibles, and form compounds, many of which are of considerable importance. These compounds are denoted by a word formed from the simple combustible present, and terminating in *uret*. Thus, *sulphuret of tin* is a compound of sulphur and tin. In like manner, *carburet* and *phosphuret of iron*, means iron combined respectively with carbon and with phosphorus. Hydrogen gas dissolves some of the metals. These solutions are denoted by prefixing the metal converted into an adjective before the word hydrogen. Thus, *arsenical hydrogen gas* means a solution of arsenic in hydrogen gas. When hydrogen combines with a metal, and forms a solid compound, it is denoted by the term *hydroguret*.

4. The metals are not known to combine with simple incombustibles. But they combine with each other, and form a set of important compounds, called *alloys*. Thus *brass* is an *alloy* of copper and zinc; and *bell-metal* an *alloy* of copper and tin. When mercury is one of the metals combined, the compound is not called an alloy, but an *amalgam*. Thus, the amalgam of gold is gold dissolved in mercury.

5. The metals at present known (excluding the new ones discovered by Davy, which will be better described afterwards) amount to 27. They may be divided into the four following sets:

List of metals.

I. *Malleable.*

1. Gold.
2. Platinum.
3. Silver.
4. Mercury.
5. Palladium.
6. Rhodium.
7. Iridium.
8. Osmium.
9. Copper.
10. Iron.
11. Nickel.
12. Tin.
13. Lead.
14. Zinc.

II. *Brittle, and easily Fused.*

1. Bismuth.
2. Antimony.
3. Tellurium.
4. Arsenic.

III. *Brittle, and difficultly Fused.*

1. Cobalt.
2. Manganese.
3. Chromium.
4. Molybdenum.
5. Uranium.
6. Tungsten.

IV. *Refractory.*

1. Titanium.
2. Columbium.
3. Cerium.

The fourth set consists of metals which have not hitherto been obtained in quantities, except in the state of oxides. Formerly the brittle metals were called *semimetals*, and the malleable, *metals*. The first four malleable metals were once considered as *noble*, because their oxides may be reduced by mere heat.

Sect. I. *Of Gold.*

Gold.

Gold seems to have been the first known of all the metals. As it occurs always in the metallic state, and is very soft and ductile, less skill would be necessary to work it.

Properties.

1. Gold has a yellow colour, considerable lustre, and is destitute of taste or smell. It is very soft. Its specific gravity is 19.376, that of water being 1.000. It is the most ductile and malleable of all known bodies. It may be beaten out into leaves only $\frac{1}{280000}$th part of an inch in thickness, and drawn out into wire extremely fine. Its tenacity is considerable; a gold wire, 0.078 inch in diameter, being capable of supporting 150.07 lbs. avoirdupois without breaking.

It melts at 32° Wedgewood, and, when melted, has a bluish green colour. It does not sensibly waste nor alter, though kept very long in the state of fusion. In very violent heats, however, it has been perceived to be partially volatilized. When carefully cooled after fusion, it sometimes crystallizes in four-sided pyramids. Gold is not altered by exposure to the air; it does not even lose its lustre.

Oxides.

2. It combines with oxygen, and forms different oxides, the number and properties of which are but imperfectly known. Two have been described. The first, or the purple, is formed when violent electrical explosions are passed through gold leaf, or when gold is subjected to combustion. It is probably a compound of 100 gold and 8 oxygen.

The second, or peroxide, is of a yellow colour. It may be obtained by dissolving gold in nitro-muriatic acid, and then precipitating the metal by means of lime-water. It falls in the state of this yellow oxide. When carefully washed and dried, it is insoluble in water, and tasteless. From an experiment of Proust, we may infer, that it is composed of 100 gold and 32 oxygen.

It combines with chlorine, and forms the yellow-coloured, deliquescent, strong-tasted salt, at present distinguished by the name of *muriate of gold*.

3. Hitherto gold has been united with only one of the simple combustibles, namely phosphorus. Hydrogen and charcoal are said to precipitate it from its solutions in the metallic state. With sulphur it does not combine. The action of boracium has not been tried.

Phosphuret.

The compound of phosphorus and gold is called *phosphuret of gold*. It may be formed by dropping small pieces of phosphorus into gold in fusion. It is brittle, whiter than gold, and contains $\frac{1}{24}$th of phosphorus. The phosphorus may be dissipated by exposing the compound to a sufficient heat.

4. As far as is known, gold does not combine with azote.

5. It combines readily with most of the metals, and forms a variety of alloys.

Alloys.

Gold is so soft, that it is seldom employed quite pure. It is almost always alloyed with a little copper or silver. Goldsmiths usually announce the purity of gold in the following manner. Pure gold is divided into 24 parts, called *carats*. Gold of 24 carats, means pure gold; gold of 23 carats, means 23 parts of gold alloyed with 1 part of some other metal; gold of 22 carats, 22 parts of gold alloyed with 2 parts of some other metal. The number of carats mentioned specifies the pure gold, and what that number wants of 24 indicates the quantity of alloy. The gold coin of this country, or *sterling* gold, as it is called, is gold of 22 carats. Jewellers' gold is gold of 18 carats.

Sect. II. *Of Platinum.*

Platinum.

Platinum, which approaches to gold in many of its properties, was unknown in Europe as a peculiar metal till 1749. Hitherto it has been found only in South America, in St Domingo, and in the silver mine of Guadal-canal in Spain. For the first accurate investigation of its properties, we are indebted to Dr Lewis; and since his time it has been investigated by a great number of very eminent chemists.

It is brought from America in small flat grains, having a silvery lustre. These grains, besides platinum, contain no less than eight other metals. The platinum may be obtained pure, by dissolving the grains in nitro muriatic acid, and pouring a solution of *sal ammoniac* into the liquid. An orange yellow precipitate falls. This precipitate is to be washed and dried, and exposed to a red heat. The powder which remains is pure platinum. It may be amalgamated with mercury; and, by cautious heating and hammering, it may be reduced into an ingot.

Properties.

1. Platinum has a white colour like silver, but not so bright. It is as hard as iron. Its specific gravity, when hammered, is at least 23, so that it is the heaviest of all known bodies. It is very ductile and malleable. A platinum wire of the diameter 0.078 inch, is capable of supporting 274.31 lbs. avoirdupois without breaking. It is very difficult of fusion, and indeed cannot be melted in any quantity by the greatest heat which we can produce. But at a white heat, pieces of platinum may be welded together like pieces of hot iron. It is not altered by the action of heat and air.

Oxides.

2. Platinum cannot be converted into an oxide by the action of heat and air; we must have recourse to the action of acids. There are two oxides of platinum known: the protoxide is green, the peroxide brown.

The peroxide may be obtained by pouring lime water into the solution of platinum in nitro-muriatic acid. The brown powder which precipitates is to be dissolved in nitric acid, the solution evaporated to dryness, and the acid driven off by a cautious application of heat. The brown powder which remains is the peroxide. It is tasteless, insoluble in water, and decomposed by a red heat. It is composed, according to Mr Chenevix's experiments, of

87 platinum,
13 oxygen.

100

If the peroxide is gradually heated, it assumes a green colour, owing to the separation of a quantity of oxygen. This green powder is the protoxide, composed of

93 platinum,
7 oxygen.

100

Chlorine combines with platinum, and forms the dark brown substance distinguished by the name of muriate of platinum.

Phosphuret.

3. The simple combustibles have but little action on platinum. Neither hydrogen nor carbon unites with it. Phosphorus combines readily, and forms a *phosphuret*. It may be obtained by projecting phosphorus on red hot platinum. Its colour is silver white; it is very brittle and hard, and easily melts. The phosphorus may be driven off by heat. Platinum cannot be made to unite with sulphur. In this respect it resembles gold.

4. Azote does not combine with platinum.

Alloys.

5. It combines with most of the other metals, and forms alloys, first examined by Dr Lewis.

Gold unites to it, but a strong heat is necessary to combine them uniformly. Platinum alters the colour of gold very much. An alloy of four parts of gold and one of platinum has the colour of pure platinum. The colour is much affected, unless the platinum be less than $\frac{1}{17}$th of the gold. If such an alloy be digested in nitric acid, the platinum is dissolved. Thus it is easy to detect any attempt to debase gold by the addition of platinum.

SECT. III. *Of Silver.*

Silver.

Silver seems to have been known almost as early as gold.

Properties.

1. It has a fine white colour, with a shade of yellow, and is remarkably brilliant when polished. It is rather harder than gold. Its specific gravity is about 10.510. In malleability and ductility, it is inferior to none of the metals except gold. It may be hammered out into plates not more than $\frac{1}{100000}$th of an inch thick, and drawn out into wire finer than a human hair. A silver wire 0.078 inch thick, is capable of supporting 187.13 lbs. avoirdupois, without breaking. It melts when thoroughly red hot, or at the temperature of 22° Wedgewood. By a very violent heat it may be boiled, and partly volatilized. When cooled slowly, it crystallizes in four-sided pyramids.

Oxides.

2. By very long exposure to heat and air, silver may be oxidized; but the process is so tedious and difficult, that we cannot have recourse to it. There are two oxides of silver known, both of which have an olive green colour.

The peroxide may be formed by dissolving silver in nitric acid, and precipitating, by means of lime water. The powder which falls, when washed and dried, is the peroxide. It is tasteless and insoluble in water. When exposed to light or to heat, it is decomposed, and the silver reduced. It is composed of about

92.67 silver,
7.33 oxygen.

100

The protoxide may be formed by heating the solution of silver in nitric acid, in contact with a quantity of granular silver. It resembles the peroxide in colour, but its combination with nitric acid is more soluble.

Chlorine combines with silver, and forms with it the white-coloured, insoluble, and tasteless substance, at present distinguished by the name of muriate of silver.

3. Neither hydrogen nor carbon have been combined with silver; but it combines readily with sulphur and phosphorus.

Sulphuret.

When thin plates of silver and sulphur are laid alternately in a crucible, they melt by a moderate heat, and form sulphuret of silver. This compound is found in silver mines, or it exists *native*, as mineralogists term it. It has a dark grey colour, a metallic lustre, and the softness, flexibility, and malleability of lead. Its specific gravity is 7.2. It is composed of 87.27 silver, and 12.73 sulphur. When silver plate is long exposed, it contracts a thin covering of this substance. Hence the tarnish of silver is owing to its combining with sulphur.

Phosphuret.

Phosphuret of silver may be formed by projecting phosphorus into melted silver. It is white, composed of grains, breaks under the hammer, but may be cut with a knife. It is composed of four parts of silver and one of phosphorus. Heat decomposes it, by dissipating the phosphorus.

4. Silver does not combine with azote.

5. It combines readily with most of the metals.

Alloys. When gold and silver are melted together, they combine spontaneously, in the proportion of one part of silver and five of gold. They may, however, be melted together, and mixed in any proportion whatever. This alloy is harder and more sonorous than pure gold. Its hardness is a maximum when the alloy consists of two parts gold and one silver. The density of the alloy is a little diminished, and the colour of the gold is much altered, even when the proportion of silver is small. It is not only pale, but has a very sensible greenish tinge.

Silver and platinum may be combined by fusion, and form a hard alloy, not so ductile as silver. The two metals separate when the alloy is kept in fusion. Hence there appears but little affinity between them.

SECT. IV. *Of Mercury.*

Mercury. *Mercury*, called also *quicksilver*, was known to the ancients, and applied by them to the same purposes as it is by the moderns.

Properties. 1. Its colour is white, like that of silver; it has a good deal of lustre, and is destitute of taste and smell. Its specific gravity is 13.568. At the common temperature of the atmosphere, it is always in a state of fluidity. But if it be cooled down to 39° below zero, it becomes solid like any other metal. The congelation of mercury by cold was accidentally discovered by Professor Braun, at Petersburgh, in 1759. The freezing point was ascertained by Mr Hutchins, at Hudson's Bay, in consequence of the directions of Mr Cavendish. Solid mercury is malleable; but neither the degree of its malleability nor its ductility have been ascertained by experiment. Mercury boils when heated to 656°. Its vapour is invisible and elastic like air. It may be easily distilled over in proper vessels, and by this means is obtained pure.

Oxides. 2. Mercury is not altered by being kept in water. But when long agitated in air, or when kept heated in the open air, it gradually loses its metallic appearance, and is oxidized. Only two oxides of mercury have been yet ascertained in a satisfactory manner, the *protoxide*, which is *black*, and the *peroxide*, which is *red*.

The protoxide is a black powder, which may be obtained by agitating mercury for a long time in a stout phial; or by heating the salt called *calomel*, or *muriate of mercury*, with a solution of potash. It is black, insoluble in water, and contains about 5 per cent. of oxygen.

The red oxide, called also *red precipitate*, may be obtained by keeping mercury for several days, nearly at the boiling point, in a tall glass vessel, so contrived as to prevent the evaporation of the mercury, and admit a communication between the interior of the vessel and the atmosphere. The mercury becomes at first black, and gradually changes to red. It may be formed more speedily and easily by dissolving mercury in nitric acid, evaporating the solution to dryness, and heating the dry salt gradually, almost to redness, in a crucible or capsule. Nitric acid fumes exhale, and the whole assumes a fine red colour. The red oxide of mercury has an acrid and disagreeable taste, acts as an escharotic, and possesses poisonous qualities. When heated with zinc or tin filings, it sets them on fire. It contains about 10 per cent. of oxygen. When heated it gives out oxygen gas, and the mercury is reduced.

3. Mercury does not combine with hydrogen or carbon; but unites readily with sulphur and phosphorus.

Sulphurets. When two parts of sulphur and one of mercury are triturated together in a mortar, they gradually assume the appearance of a black powder, formerly called *æthiops mineral*. The same compound is formed by adding mercury slowly to its own weight of melted sulphur. When formed by the first process, the powder is black, but a microscope detects in it small globules of mercury; when formed by the second process, the powder is black, with a shade of purple. This compound has been ascertained to consist of mercury and sulphur united together, in what proportion is not well known.

When this black sulphuret is exposed to a red heat in a glass vessel, it sublimes and forms a cake of a fine scarlet colour. In this state it is usually called *cinnabar*, and when reduced to a fine powder, *vermilion*. It is well known as a red paint. Its specific gravity is about 10. It is tasteless, insoluble in water and in muriatic acid. When suddenly heated it burns with a blue flame. When mixed with iron filings, and distilled, it is decomposed, and running mercury obtained in the receiver. It is composed of about 85 parts mercury and 15 sulphur.

When phosphorus is mixed with the black oxide of mercury, and exposed to heat, the mixture readily combines, forming a black mass, which seems to be phosphureted oxide of mercury. At least phosphorus and mercury do not unite when heated together.

4. Mercury does not unite with azote.

Amalgams. 5. It combines with most metals, and forms compounds called *amalgams*.

The amalgam of gold is formed very readily by throwing small pieces of red hot gold into hot mercury. The two metals combine in any proportion. The amalgam is white and fluid if the mercury exceed. But by squeezing it through leather, the excess of mercury separates, and a solid amalgam remains, of the consistence of butter, which gradually crystallizes. It consists of one part of mercury to two of gold. This amalgam is much used in gilding.

The amalgam of platinum may be formed by triturating the powder of platinum with mercury, adding gradually a portion of either ingredient, till the combination is completed. When the process of amalgamation is once begun, it goes on easily. This amalgam has the consistence of butter, a white colour, much lustre, and does not tarnish by keeping. The mercury may be driven off by heat.

The amalgam of silver may be made in the same manner as that of gold, and with equal ease. It has a white colour, is always soft, and crystallizes.

All these amalgams are decomposed, and the mercury driven off by heat.

Sect. V. *Of Palladium.*

Palladium.

This metal was lately discovered by Dr Wollaston, in crude platina. Mr Chenevix announced soon after that he had succeeded in forming this metal artificially, by combining together platinum and mercury; but as nobody has been able to repeat his experiment with success, we must suppose him mistaken.

To obtain palladium, dissolve a sufficient quantity of crude platina in nitro-muriatic acid, and pour a solution of the salt called *prussiate of mercury* into the liquid. A yellowish white powder falls. When this powder is washed and dried, and exposed to a red heat, it leaves a white matter, which is *palladium*. When strongly heated with sulphur and borax, it may be melted into a button.

Properties.

1. Palladium thus obtained is a white metal, very like platinum in its appearance. Its specific gravity, when hammered, is 11.871. It is as malleable as platinum, breaks with a fibrous fracture, and appears of a crystallized texture. It is not altered by exposure to the air, and a very violent heat is necessary to fuse it.

2. When kept strongly heated, its surface acquires a blue colour. This is supposed a commencement of oxydizement. A more violent heat makes it resume the original metallic appearance. Sulphuric, nitric, and muriatic acids dissolve a portion of it when assisted by heat, and assume each a red colour. Nitro-muriatic acid is the best solvent of it.

3. Neither hydrogen nor carbon combine with this metal. But when brought into contact with sulphur while red hot, it melts immediately, and the sulphuret formed continues in fusion till only obscurely red. It is rather paler than the pure metal, and very brittle.

4. The simple incombustibles do not combine with palladium; but it unites with the metals, and forms alloys, which have been examined and described by Mr Chenevix.

Sect. VI. *Of Rhodium.*

Rhodium.

This metal exists also in crude platina, and was discovered by Dr Wollaston still more recently than the last.

How procured.

The process followed by Dr Wollaston for obtaining it, is somewhat complicated. Crude platina is dissolved in nitro muriatic acid, and the platinum precipitated by sal ammoniac. A piece of clean zinc is immersed into the residuary solution, which throws down a black powder. This black powder is digested with dilute nitric acid in a very gentle heat, to dissolve some copper and lead with which it is frequently contaminated. It is then dissolved into nitro-muriatic acid, common salt is added to the solution, and the whole is gently evaporated to dryness. The residuum is washed repeatedly with small quantities of alcohol, which dissolves two salts, consisting of the oxides of platinum and palladium in combination with common salt. There remains behind a deep red-coloured substance, consisting of the oxide of rhodium united to common salt. By solution in water, and gradual evaporation, rhomboidal crystals of a deep red colour are obtained. These crystals being dissolved in water, and a plate of zinc immersed into the solution, a black powder precipitates, which being strongly heated with borax, becomes white, and assumes a metallic lustre. In this state it is *rhodium*.

Propertie

1. Rhodium thus obtained, is white. Its specific gravity exceeds 11. No degree of heat hitherto applied is sufficient to melt it. Of course its malleability and other similar properties are unknown.

2. It is not oxidized by exposure to heat and air. Neither is it much acted on by acids. The only oxide of rhodium known is of a yellow colour. It may be obtained by dissolving the red crystals mentioned above, and precipitating by means of potash. This oxide, when dissolved in nitric or muriatic acid, does not crystallize.

3. It unites readily with sulphur, and by that means is easily melted. When the sulphur is driven off by heat, the metallic button obtained is not malleable. The action of the other simple combustibles is not known.

4. It does not combine with the simple incombustibles. It forms alloys with all the metals tried by Dr Wollaston, except mercury, with which it does not combine. It does not, like platinum and palladium, destroy the colour of gold when alloyed with it.

Sect. VII. *Of Iridium.*

Iridium.

How procured.

This metal was discovered by Mr Smithson Tennant, in 1803. Attempts were made by Descostils, and by Fourcroy and Vauquelin soon after, to obtain the same metal, but they succeeded but imperfectly.

When crude platina is dissolved in nitro-muriatic acid, a black powder remains, which preceding chemists considered as plumbago, but which Mr Tennant ascertained to be a compound of two new metals. When kept for some time in a red heat, mixed with its own weight of potash in a platinum crucible, water poured on the mixture forms a deep orange-coloured solution. Muriatic acid being digested on the powder which remains, becomes first blue, then green, and at last deep red. By repeated fusions with potash, and digestions in muriatic acid, the whole of the black powder is decomposed and dissolved. The potash solution contains the metal called *osmium*; the muriatic acid solution the metal called *iridium*.

A piece of zinc being put into this last solution, precipitates a black powder; when heated it becomes white, and is *iridium*.

Propertie

1. It has the appearance of platinum, and seems as difficult of fusion as that metal. It resists the action of acids, even the nitro-muriatic, almost completely.

2. Its affinity for oxygen seems weak; but, like other metallic bodies, it unites with that principle. The change of colour which its solution in muriatic acid assumes, seems to prove that it is capable of combining with different dozes of oxygen. When the colour is *blue*, the metal seems oxidized to a minimum; when *red*, it seems oxidized to a maximum.

3. The simple combustibles do not seem to com-

bine with iridium. Mr Tennant did not succeed in his attempt to unite it with sulphur.

4. It formed alloys with all the metals tried except arsenic. It does not alter the colour of gold, and cannot be separated from gold and silver by cupellation.

SECT. VIII. *Of Osmium.*

Osmium. This metal was discovered by Mr Tennant at the same time with the preceding. It exists in the black powder separated during the solution of crude platina, and may be obtained in solution in potash, by the process described in the last Section. When sulphuric acid is mixed with this solution, and the whole subjected to distillation, a colourless liquid comes over, consisting of water, holding the oxide of osmium in solution. It has a peculiar smell. Hence the name *osmium* applied to the metal. When mercury is agitated in this solution, the osmium combines with it, and leaves the water, and by applying heat, the mercury is driven off, and the metal obtained in a state of purity.

Properties. 1. Osmium has a dark grey or blue colour, and the metallic lustre. In the open air it is easily dissipated by heat; but in close vessels, it resists any degree of heat without alteration. It is not acted on by any acid, not even the nitro-muriatic, but is easily obtained in solution by the action of potash.

2. Osmium is easily oxidized by heat in the open air. The oxide has a peculiar smell, and a kind of oily appearance. It is volatile and soluble in water. The solution is colourless, does not alter vegetable blues, and strikes first a purple, then a blue, with the infusion of nut-galls.

3. The action of the simple combustibles on this metal is not yet known. Neither do we know much of its combination with other metals. It amalgamates with mercury, and Mr Tennant united it by fusion with copper and gold.

SECT. IX. *Of Copper.*

Copper. Copper seems to have been known as early as any metal except gold and silver. It was very much employed by the ancients before the method of manufacturing steel became familiar.

Properties. 1. Copper has a fine red colour, but it soon tarnishes when exposed to the air. Its taste is styptic and nauseous, and when rubbed it emits a disagreeable odour. It is very poisonous when taken internally. It is softer than iron, but harder than gold. Its specific gravity, when pure, is about 8.9. Its malleability and ductility are very considerable. A copper wire 0.078 inch in diameter is capable of supporting 302.2 lbs. avoirdupois without breaking. It melts at 27° Wedgewood, and gradually evaporates in visible fumes. When melted, it has a bluish green colour, something like that of melted gold. When allowed to cool slowly, it crystallizes in quadrangular pyramids.

Oxides. 2. It is not altered though kept under water. When heated in contact with air, it is gradually converted into a black oxide by the combination of oxygen. Before a blow-pipe of oxygen and hydrogen gases, it burns with a fine green flame. There are two oxides of copper. The protoxide is found naturally of a red colour, but when formed artificially it is orange. The peroxide is black.

The protoxide was first recognised by Mr Proust. It may be prepared by beating together a mixture of equal parts of black oxide and copper in powder in muriatic acid. Almost the whole is dissolved, and the solution is colourless. By pouring potash into the solution, the protoxide precipitates in the state of a yellow powder. This oxide is composed of 88.89 parts copper, and 11.11 oxygen. It attracts oxygen with such avidity, that it can scarcely be dried without becoming black.

The peroxide of copper is easily formed by keeping copper filings a sufficient time red hot. It contains 80 parts copper, and 20 oxygen. It is black. It combines with water, and forms a blue-coloured matter called *hydrate of copper.*

3. Copper has not been combined with hydrogen or carbon; but it unites with sulphur and phosphorus, forming the *sulphuret* and *phosphuret of copper.*

Sulphurets. When equal parts of sulphur and copper are stratified in a crucible, they combine at a red heat, and form sulphuret of copper, of a very deep blue colour. It is brittle, and composed of 78 copper and 22 sulphur. If copper filings and sulphur in powder be mixed, and gradually heated in a flask, they combine before they are heated to redness; but at the instant of combination, a quantity of heat is evolved sufficient to convert the sulphuret into a glowing red, as if in a state of vivid combustion.

Sulphuret of copper is capable of combining with an additional dose of sulphur, and forming a *supersulphuret.* It is brittle, has a yellow colour, and the metallic lustre. It is found native, and known under the name of *copper pyrites.*

Phosphurets. Phosphuret of copper may be formed by projecting phosphorus on red hot copper. It is white, tough but not ductile, hard, and contains the 5th of its weight of phosphorus. When repeatedly melted, it still retains about 1-12th of its weight of phosphorus, and then has much the appearance of steel, and admits of an equally fine polish.

4. Copper does not combine with azote.

Alloys. 5. It combines with most of the metals, and some of its alloys are of considerable importance.

Copper unites readily with gold, and even heightens the colour, while it increases the hardness, and does not injure the ductility. Gold coin consists of gold alloyed with copper or silver, or with both. Our coin contains 1-12th of alloy, usually both silver and copper. A pound of standard gold is coined into 44½ guineas.

Platinum combines with copper, but a violent heat is necessary. The alloy is white, hard, ductile, takes a fine polish, and is not liable to tarnish. Hence it has been proposed for the mirrors of telescopes.

Copper and silver easily unite by fusion. The alloy is harder and more sonorous than silver, and retains its white colour even when the proportion of copper is considerable. Our silver coin consists of 12⅓ silver, alloyed with one of copper. A pound of standard silver is coined into 62 shillings.

Copper may be united to mercury by pouring a small stream of it melted into mercury, heated nearly to the boiling point; or by keeping plates of copper in a solution of mercury in nitric acid. It is white, and at first soft, but gradually hardens when exposed to the air.

Sect. X. *Of Iron.*

Iron. Iron was not known at so early a period as gold, silver, and copper. The art of working it was discovered in the East, and first communicated to the Greeks by the Phrygians, from whom it gradually made its way through the rest of Europe.

Properties. 1. Iron has a bluish white colour, a styptic taste, and emits a smell when rubbed. It is one of the hardest of the metals. Its specific gravity varies from 7.6 to 7.8. It is attracted by the magnet or loadstone, and is itself the substance which constitutes the loadstone. When iron is perfectly pure, it retains the magnetic virtue but a short time.

It is malleable in every temperature, and its malleability increases with the temperature. It cannot be hammered into so thin plates as gold or silver. But it may be drawn out into very fine wire. An iron wire of 0.078 inch in diameter is capable of supporting 549.25 lbs. avoirdupois without breaking. When heated to 158° Wedgewood, it melts; a temperature so high, that it is difficult to go much beyond it.

Oxides. 2. It is much more easily converted into oxide than any of the metals described in the preceding Sections. When left exposed to the air, especially in a moist place, it is soon converted to a red or yellow powder, called *rust*, which is nothing else than an *oxide* of iron usually combined with carbonic acid. When kept under water, especially in warm weather, it is gradually converted into a black brittle matter, which is also an oxide, while some hydrogen gas is disengaged, owing to the decomposition of the water. If vapour of water be passed through red hot iron, the iron is rapidly oxidized and much hydrogen gas is obtained. If an iron wire, having a small bit of lighted cotton at its extremity, be plunged into a jar of oxygen gas, it burns with great brilliancy, and is converted into the same black oxide, which falls to the bottom of the jar in melted drops.

There are two oxides of iron, which have been ascertained in a satisfactory manner. The *black* oxide may be obtained, by keeping iron filings a sufficient time in water, by making steam pass through iron filings at a red heat, by burning iron wire in oxygen gas, or by dissolving iron in diluted sulphuric acid, and dropping potash into the solution. It is a black powder, insoluble in water, is attracted by the magnet, and has a good deal of metallic lustre. It is a compound of 78.5 parts iron and 21.5 oxygen.

The *red oxide*, or *peroxide*, may be obtained, by keeping iron filings red hot in an open vessel, and agitating them constantly till they are converted into a red powder; or by exposing a solution of iron in sulphuric acid for a long time to the atmosphere, and then precipitating by means of potash. It is a red powder, insoluble in water, and constitutes the base of several of the common red paints. Clay and bricks owe to it their yellow and red colours. It is composed of 69 iron and 31 oxygen.

3. Iron seems capable of combining with all the simple combustibles. Hydrogen, indeed, has never been united to it in a solid state, but hydrogen gas dissolves a little iron, which it gradually deposits when kept over water.

Carburet. Carburet of iron is found native, and is the substance mentioned in a preceding Section under the name of *plumbago*, or *black lead*. It is a soft substance, of a dark blue colour, a granular texture, and the metallic lustre. It does not burn with a flame, but gradually wastes away when kept red hot. When thrown into melted nitre, a very splendid combustion is produced. Its nature was first developed by Dr Lewis, and afterwards more fully explained by Scheele and the French chemists. It seems to consist of about 19 parts of carbon, and one of iron.

Phosphurets. Phosphuret of iron may be formed by dropping bits of phosphorus upon red hot iron. Its colour is dark steel grey, it is very brittle, and does not easily dissolve in acids. It exists in different ores of iron, and is considered as giving to the variety of iron called *cold short iron*, the property of being brittle while cold, though it be malleable while hot. Phosphuret of iron was at first considered by Bergman as a peculiar metal, and called *siderum*.

Sulphurets. Sulphuret of iron may be formed, by melting together in a crucible equal parts of iron filings and flowers of sulphur. It is of a black or very deep grey colour, brittle, and very hard. When the two constituents of it combine, a great quantity of heat is evolved, which makes the whole strongly red hot. This sulphuret is composed of 63 iron and 37 sulphur. It exists native, and is known by the name of *magnetic pyrites*. Its colour is that of bronze; it has the metallic lustre, but its powder is blackish grey. Its specific gravity is 4.518. It strikes fire with steel, and easily melts when heated. It is not only magnetic, but is itself capable of being converted into a permanent magnet, as Mr Hatchett discovered.

Iron is capable of combining with a still greater proportion of sulphur, and of forming a compound which may be called *super-sulphuret of iron*. It occurs native in great abundance, and is known by the name of *pyrites*, or *iron pyrites*. It is yellow, has the metallic lustre, is brittle, strikes fire with steel, and is often crystallized in cubes. Its specific gravity is 4.5. When distilled, it loses its excess of sulphur, and is converted into common sulphuret of iron. By this process, sulphur is sometimes obtained for the purposes of manufactures. Pyrites is composed of 80 common sulphuret of iron and 20 sulphur, or more exactly of about 47 iron and 53 sulphur. The super-sulphuret is not magnetic, nor susceptible of becoming a magnet. Mr Hatchett found, that phosphuret of iron is also capable of magnetic impregnation; and it is well known that iron containing a portion of carbon, or *steel*, possesses the same property in perfection. Hence Mr Hatchett concludes, that permanent magnets consist of iron, combined with a certain proportion of a simple combustible. But, when saturated with simple combustibles, it loses its magnetic properties entirely. This is known with respect to iron saturated with sulphur and carbon, and is probable with respect to iron saturated with phosphorus. The subject requires and deserves farther investigation.

There are a great many varieties of iron, which artists distinguish by different names; but they may be all reduced under the following classes: *Cast iron*, *wrought* or *soft iron*, and *steel*.

Cast iron.

Cast iron, or *pig iron*, is the name of the metal when first extracted from its ores. The ores of iron commonly used, are a mixture of the oxide of the metal and clay. They are reduced to small pieces, and exposed to a violent heat, mixed with charcoal and lime. The charcoal separates the oxygen, while the lime, combining with the clay, forms a liquid through which the melted iron falls, and is collected at the bottom of the furnace. It is let out and cast in moulds. The cast iron thus obtained, varies considerably according to circumstances. Three varieties have been well distinguished; namely, *white* cast iron, which is very hard and brittle; *grey* or *mottled*, which is softer and less brittle; and *black*, which is the softest and most fusible. Cast iron melts at 130° Wedgewood. Its specific gravity varies from 7.2 to 7.6. It contracts considerably when brought into fusion.

Cast iron is converted into *wrought or soft iron*, by keeping it melted for a considerable time in a bed of charcoal and ashes, and the *scoriæ* or *black oxide* of iron, and then forging it repeatedly till it becomes compact and malleable. In this state, it is the substance described in the beginning of this Section under the name of *iron*. It is considered when pure as a simple body; but it is difficult to procure it quite pure. It is almost always contaminated with some foreign body, either some of the other metals, or oxygen, carbon, or phosphorus.

When soft iron is kept red hot for some time in a bed of charcoal, it is converted into *steel*. Steel is so hard, as to be unmalleable while cold. It is brittle, resists the file, cuts glass, strikes fire with flint, and retains the magnetic virtue when impregnated with it. It is more sonorous; and its specific gravity is greater than than that of soft iron. It varies from 7.78 to 7.84.

Steel.

These different states of iron have been long known, and many attempts were made to ascertain the cause of the differences among them. At last it was recognised by Bergman and the French chemists. Soft iron is the simple metal. *Steel* is iron combined with a portion of carbon, and has been for that reason called *subcarburet of iron*. The carbon, from Vauquelin's analysis, amounts to $\frac{1}{140}$th part of the whole. *Cast iron* is iron combined with a still greater proportion of carbon. It usually contains likewise a little oxygen.

4. Iron does not combine with azote.

Alloys.

5. Iron unites with most of the metals. Gold combines readily with iron, and forms a ductile alloy of a pale yellow or white colour, according to the proportions. Platinum is found usually alloyed with iron, but it is difficult to combine the two metals artificially, on account of the high temperature necessary to fuse them. Silver and iron combine, and form a very hard alloy of a white colour. Mercury does not readily unite to iron, but an amalgam may be formed artificially. Iron may be united to copper by fusion, but not without considerable difficulty. The alloy is grey, imperfectly ductile, and very infusible. It is probable that the variety of iron called *hotshort*, because it is brittle when red hot, owes that property to the presence of a little copper with which it is alloyed.

Sect. XI. *Of Nickel.*

Nickel.

Nickel was first recognised as a peculiar metal, in consequence of the experiments of Cronstedt in 1751. It is obtained from an ore which occurs in different German mines, and called *kupfer nickel*, or false copper, because it resembles copper, though no copper can be extracted from it. It has been examined by many eminent chemists, especially by Richter, to whom we are indebted for the most exact account of its properties.

Properties.

1. Nickel has a white colour like silver; it is softer than iron; its specific gravity, when hammered, is 8.820. It is malleable both cold and hot, and may be easily hammered out into thin plates. It is powerfully attracted by the magnet, and may be converted into a magnet precisely like bars of steel. It requires for fusion a temperature at least equal to 160° of Wedgewood. It is not altered by air nor water.

Oxides.

2. When moderately heated, it tarnishes; and, if in powder, may be even converted into an oxide; but a strong heat reduces it again to the metallic state. We are at present acquainted with two oxides of nickel, the *grey* and the *black*.

The protoxide may be obtained by dissolving nickel in nitric acid, precipitating the oxide by carbonate of potash, washing it, and exposing it to a slight red heat. It is of an ash grey colour, and is composed of 78 nickel, and 22 oxygen. It is tasteless, soluble in muriatic acid, and the solution is grass green. It dissolves likewise in ammonia.

The peroxide may be formed by mixing the protoxide with water, and passing a current of chlorine gas through the liquid. A portion of the oxide dissolves, and a portion acquires a black colour. When this black oxide is dissolved in acids, an effervescence takes place, owing to the escape of a portion of its oxygen.

3. Nickel has not been combined with hydrogen. It is always united with carbon, and it unites readily with phosphorus and sulphur. Cronstedt formed sulphuret of nickel by fusion. The phosphuret may be obtained by dropping bits of phosphorus on red hot nickel.

4. Nickel does not unite with the simple incombustibles.

5. The alloys which it forms are but imperfectly known. They are mostly brittle and hard, and have been applied to no useful purpose.

Sect. XII. *Of Tin.*

Tin.

Tin was known to the ancients, and was imported from Britain at a very early period by the Phœnicians.

Properties. 1. Tin has a fine white colour, with a shade of blue. It has a slightly disagreeable taste, and emits a peculiar smell when rubbed. It is scarcely so hard as silver. Its specific gravity, when hammered, is 7.299. It is very malleable, and may be hammered out into very thin plates; but its ductility and tenacity are much inferior. A tin wire, 0.078 inch in diameter, is capable of supporting only 34.7 pounds without breaking. When tin is bent it produces a remarkable crackling noise. It melts at 442°; and, when slowly cooled, crystallizes in rhomboidal prisms.

Oxides. 2. Tin soon tarnishes when exposed to the air; but the tarnished coat is always extremely thin. It is not altered though kept under water; but, at a red heat, it decomposes water, combines with its oxygen, and disengages the hydrogen. When kept melted, it is soon covered with a greyish matter, which becomes speedily yellow. But it is very difficult to oxidize tin completely by heat and air. Tin is capable of forming two different oxides.

The *protoxide*, or grey oxide, may be formed by dissolving tin in muriatic acid by means of heat, and adding potash in excess to the solution. A white powder falls, which is gradually converted into a grey matter, having a good deal of the metallic lustre. This is the grey oxide. It is tasteless; readily soluble in acids; and greedily absorbs more oxygen. It is composed of 55 tin, and 7.5 oxygen.

The *peroxide* may be obtained by heating tin in concentrated nitric acid. A violent effervescence ensues, and the tin is converted into a white powder, which is the peroxide. It dissolves readily in potash and in muriatic acid. It is composed of 55 parts tin and 15.2 oxygen.

Chlorine readily combines with tin, and forms a curious liquid, known by the name of *fuming liquor of Libavius*.

3. Tin has not been combined with hydrogen or carbon, but it unites to phosphorus and sulphur.

Phosphuret. Phosphuret of tin may be formed by throwing bits of phosphorus on melted tin. It has the colour of silver; is soft; may be cut with a knife; and extends under the hammer, but separates into laminæ. It is composed of 85 tin and 15 phosphorus.

Sulphurets. Sulphuret of tin may be formed by fusing the two ingredients together in a crucible. It is brittle, heavier than tin, and not so fusible. It is of a bluish colour, laminated texture, and capable of crystallizing. It contains 15 parts of sulphur and 55 of tin.

When equal weights of peroxide of tin and sulphur are gradually heated in a retort, some sulphur and sulphurous acid are disengaged, and there is formed a substance called *Mosaic gold*, or *aurum musivum*. It consists of gold-coloured flakes, light, and adhering readily to the skin. Proust has endeavoured to shew, that this substance is a compound of sulphur and protoxide of gold; but his proofs are insufficient. Neither nitric nor muriatic acid acts upon it, but it dissolves in hot nitro-muriatic acid, and is gradually changed into *sulphate of tin*. It dissolves in liquid potash when assisted by heat, and deflagrates when heated with twice its weight of nitre. It consists of tin combined with twice as much sulphur as exists in sulphuret of tin.

4. Tin does not unite with the simple incombustibles, but it combines with the metals, and forms alloys, some of which are of considerable importance.

Alloys. With gold it unites easily by fusion, and was thought formerly to render the metal very brittle; but the experiments of Alchorne, Hatchett, and Bingley, have shewn that this opinion is, to a considerable degree, erroneous. Tin readily melts with platinum, and forms a brittle alloy, unless the proportion of platinum does not exceed one-ninth of the alloy. The alloy of tin and silver is very brittle and hard. Mercury dissolves tin with facility, and forms an amalgam capable of crystallizing. It is used for silvering the backs of looking glasses.

Tin unites readily with copper, and forms an alloy known by the names of *gun metal*, *bell-metal*, *bronze*, and *mirrors of telescopes*, according to the proportion of the ingredients. Tin diminishes the ductility of copper, and increases its hardness, tenacity, fusibility, and sonorousness. The specific gravity is greater than the mean, and is a maximum when the alloy is composed of 100 copper and 16 tin.

Bronze and gun-metal are composed of 100 parts of copper and from 8 to 12 of tin. Brass guns are made of it. The ancients used it for making cutting instruments. The *χαλκὸς* of the Greeks, and the *æs* of the Romans, was nothing else.

Bell-metal is usually composed of 3 parts of copper and 1 of tin. It is greyish white, very hard, sonorous, and elastic. The mirrors for telescopes consist of about 2 parts copper and 1 tin. This alloy is very hard, the colour of steel, and admits of a fine polish.

When copper is used for culinary vessels, it is covered with a thin coating of tin, and is then known by the name of *tinned copper*. The coating of tin is extremely thin, but it completely prevents the copper from injuring the articles dressed in such vessels.

Tin does not unite readily with iron; but the two metals may be combined by fusing them together in a well closed crucible. The formation of *tin-plate* shows the affinity between the two metals. This very useful compound is made by dipping clean plates of iron into melted tin.

Sect. XIII. *Of Lead.*

Lead. Lead was very well known to the ancients, but they do not always seem to distinguish it accurately from tin; though the properties of the two metals be exceedingly different.

Properties. 1. Lead has a bluish white colour, and, when newly melted, is very bright; but it soon tarnishes when exposed to the air. It is tasteless; but, when rubbed, emits a peculiar smell. It stains the fingers or paper dark blue. When taken internally, it is poisonous. It is very soft. Its specific gravity is 11.407. It is not increased by hammering. It is very malleable; but its ductility and tenacity are not great. A lead wire, 0.078 inch in diameter, is capable of supporting only 27.7 lbs. without breaking. It melts at 612°. When slowly cooled, it crystallizes in 4 sided pyramids.

Oxides.

2. Lead soon tarnishes in the open air, but the oxidizement never proceeds far. Water does not act upon it, though it greatly facilitates the action of the external air. Lead is believed at present to be capable of forming 3 different oxides.

The *yellow oxide* is the most important, as it constitutes the basis of almost all the known salts of lead. It may be obtained by dissolving lead in nitric acid, precipitating by carbonate of potash, and heating the white powder which falls almost to redness. It is yellow, tasteless, insoluble in water, but soluble in potash and in acids. It readily melts, and forms a brittle semitransparent hard glass. It is composed of 100 lead and 7.7 oxygen. It may be formed by exposing lead for a sufficient time to the action of heat and air, and is then known by the name of *massicot.*

If yellow oxide be dissolved in nitric acid, and the solution boiled over a quantity of lead filings in a phial, the liquid assumes a yellow colour, and yields yellow, brilliant crystals, in scales. These crystals, according to Proust, consist of nitric acid united to an oxide of lead, containing less oxygen than yellow oxide. But his experiments have not been verified by subsequent inquirers.

If massicot, ground to a fine powder, be exposed in a furnace to the flame of burning coals, playing upon its surface for about 48 hours, it is converted into a beautiful red powder, called *minium,* or *red lead.* This is the *deutoxide* or *red oxide* of lead. It is of an orange red colour, of the specific gravity of 8.940; insoluble in water, but soluble in potash. When heated to redness, it gives out oxygen gas, and is partly reduced, and partly melted, to a dark brown glass. It does not combine with acids. When acids dissolve it, they first reduce it to the state of yellow oxide. It is composed of 90 lead, and 10 oxygen.

If weak nitric acid be poured upon red lead, a portion is dissolved, but a portion remains in the state of a dark *brown powder.* This brown powder is the peroxide of lead. It is tasteless, light, and is not acted on by sulphuric or nitric acid. To muriatic acid it gives out oxygen, and converts it into oxymuriatic acid. It is composed of 86.5 lead, and 13.5 oxygen.

When lead is first extracted from its ore, it almost always contains a portion of silver, which is always extracted when its quantity is sufficient to repay the expence. The process is known by the name of *refining* the lead. The lead is placed in a large flat dish, called a *test,* composed of burnt bones and fern ashes, and exposed to the flame of a furnace. The lead gradually assumes a kind of vitriform state, and is either blown off or sinks into the test, while the silver remains unaltered. The lead by this process is converted into *litharge.* It consists of fine scales, partly red and partly yellow. It is yellow oxide, combined with a small portion of carbonic acid.

3. Lead has not been combined with hydrogen or carbon, but it unites to phosphorus and sulphur.

Phosphuret.

Phosphuret of lead may be formed by dropping phosphorus into melted lead. It has a silver white colour, with a shade of blue, and soon tarnishes.

Sulphuret.

Sulphuret of lead may be formed by mixing the two ingredients and melting them in a crucible. It occurs abundantly native, and is known by the name of *galena.* It is brittle, brilliant, of the colour of lead, less fusible, and usually crystallizes in cubes. Its specific gravity is about 7. It is composed of 86.5 lead and 13.5 sulphur.

There is another sulphuret of lead, which has been occasionally found native also. The colour is lighter, and it burns with a blue flame when placed upon burning coals. It contains at least 25 per cent. of sulphur.

4. Lead does not combine with the simple incombustibles. It forms alloys with the other metals, but few of them are of much importance.

Alloys.

It renders gold as brittle as glass, when the proportion of it does not exceed $\frac{1}{1920}$th of the gold. It likewise renders platinum brittle. The alloy of silver and lead is very brittle; its specific gravity is greater than the mean. Mercury readily dissolves lead, and forms an amalgam capable of crystallizing. Copper dissolves in lead at a strong red heat. The alloy is grey and brittle, and when heated gradually, the lead melts and runs off, leaving the copper nearly pure. Iron unites with lead with difficulty, and the alloy is easily decomposed. Lead and tin may be combined in any proportion. The alloy is harder, and possesses more tenacity than tin.

SECT. XIV. *Of Zinc.*

Zinc.

The ancients do not appear to have been acquainted with this metal. It has been long known in China, and is mentioned by European writers in the 13th century. The method of extracting it from its ores was unknown in Europe till near the middle of the 18th century.

Properties.

1. Zinc has a brilliant white colour, with a shade of blue, and is composed of thin plates cohering together. It has a sensible taste, and acquires, when rubbed, a slight smell. It is rather harder than silver. When hammered, its specific gravity is 7.1908. In its usual state it can scarcely be said to be malleable; but when heated a little above 212°, it becomes very malleable, and may be rolled out into thin plates, or drawn into wire. A zinc wire 0.078th inch in diameter, is capable of supporting 109.8 lbs. When heated to about 680°, it melts, and, if cooled slowly, crystallizes in quadrangular prisms.

Oxides.

2. When exposed to the air, its surface is soon tarnished, but it hardly undergoes any other change. It is said to decompose water slowly, and to separate the hydrogen. At a red heat, the decomposition goes on rapidly. When zinc is heated to redness, it takes fire, and burns with great brilliancy, being converted into a white oxide, which flies off in fine flakes like cotton. It was called *pompholyx, nihil album, lana philosophica, flowers of zinc.*

Only one oxide of zinc is known. It is the *peroxide,* or the white oxide obtained by the combustion of the metal. It is composed of 80.39 parts zinc and 19.61 oxygen. It may be obtained likewise by dissolving zinc in sulphuric acid, and precipitating by means of potash. It is very white, light, and has some resemblance to chalk. It is tasteless and insoluble in water, and is not altered by exposure to the air.

Combinations with combustibles.

3. Most of the simple combustibles combine with zinc. Hydrogen gas, procured by the action of diluted sulphuric acid on zinc, holds a little of the metal in solution, which it gradually deposites.

Carbon was considered as an occasional constituent of zinc, and supposed to occasion the appearance of the black powder which separates when zinc is dissolved in sulphuric acid. But on examining this powder, it was found a mixture of copper and lead.

Phosphuret of zinc may be formed by dropping bits of phosphorus upon melted zinc. It has a considerable resemblance to lead. It is somewhat malleable. Phosphorus combines likewise with the oxide of zinc.

Sulphuret of zinc exists native in considerable quantity, and is known by the name of *blende*. It may be formed by fusing a mixture of sulphur and oxide of zinc.

4. Zinc does not unite with the simple incombustibles, but it combines with the metals, and forms alloys, some of which are of great importance.

Alloys.

It renders gold brittle, even when added in a very minute proportion. It melts readily with platinum, and renders it brittle. Silver readily combines with it, and forms a brittle alloy. Mercury easily amalgamates in any proportion when poured upon hot zinc. The amalgam is used to increase the energy of electric machines.

Zinc combines with copper, and forms one of the most useful of all the alloys, namely *brass*. It is prepared by mixing oxide of zinc, charcoal powder, and granular copper, and heating them sufficiently in a crucible. Brass is yellow. The proportion of zinc which it contains varies somewhat. In some British manufactures it amounts to one-third, while in Germany and Sweden it is said not to exceed one-fourth or one-fifth. Brass is much more fusible than copper. It is malleable while cold, but becomes brittle when heated. It is ductile, may be drawn into fine wire, and is much tougher than copper. When zinc in the metallic state is melted with copper, the alloy is known by the name of *pinchbeck, prince's metal, Prince Rupert's metal*. The colour of pinchbeck approaches more nearly to that of gold, but it is more brittle than brass.

Zinc cannot easily be alloyed with iron. The alloy is hard and white, and somewhat ductile. Tin and zinc easily unite. The alloy is hard and ductile. Lead and zinc may be united by fusion.

Sect. XV. *Of Bismuth.*

Bismuth.

This metal was unknown to the ancients. It was well known in Germany at the beginning of the 16th century. But chemists were long in reckoning it a peculiar metal.

Properties.

1. Bismuth is of a reddish white colour, and almost destitute of taste and smell. It is composed of broad brilliant plates adhering to one another. It is harder than silver. Its specific gravity is 9.822. When hammered cautiously, its density is increased, but it breaks when struck smartly. It cannot be drawn out into wire. A rod of one-tenth inch diameter is capable of supporting about 29 lbs. It melts at 476°, and may be distilled over in close vessels. When cooled slowly, it crystallizes in parallelopipeds.

Oxides.

2. It tarnishes in the air, but is not altered when kept under water. When kept melted in an open vessel, it is gradually converted into a yellow powder. In a strong red heat it takes fire and burns, with a faint blue flame, and emits a yellow smoke. This, when collected, is a *yellow oxide*. It is composed of about 89.3 bismuth, and 10.7 oxygen. This is the only oxide of bismuth at present known. It is tasteless and insoluble in water. When heated it melts into a brown glass.

Phosphuret.

3. Bismuth has not been combined with hydrogen or carbon. It does not seem capable of combining in any notable proportion with phosphorus. But it unites very readily with sulphur by fusion. The sulphuret is bluish grey, very brittle and fusible, and crystallizes in four-sided needles. It is composed of about 85 bismuth and 15 sulphur.

Alloys.

4. Bismuth does not unite with the simple incombustibles, but it combines with the metals, and forms alloys not hitherto applied to any useful purpose. It renders gold, platinum, and silver, brittle. It amalgamates readily with mercury. When the mercury exceeds, the amalgam is fluid, and has the property of dissolving lead, and rendering it also fluid. Bismuth renders copper and iron brittle. It facilitates the fusion of tin and lead: a mixture of eight parts bismuth, five lead, and three tin, is called fusible metal, because it melts at 212°. Bismuth does not combine with zinc.

Sect. XVI. *Of Antimony.*

Antimony.

The ancients were acquainted with some of the ores of antimony, but it does not appear that they knew the metal itself. Who first extracted it from its ores is unknown. But the process is first described by Basil Valentine.

Properties.

1. Antimony is of a greyish-white colour, and has considerable brilliancy. Its texture is laminated, and exhibits plates crossing each other in every direction. It is as hard as silver. Its specific gravity is 6.712. It is very brittle, and may be easily reduced to powder in a mortar. It melts at 810°, or when just red hot; and, when cooled slowly, forms oblong crystals perpendicular to the internal surface of the vessel in which it cools.

Oxides.

2. When exposed to the air it loses its lustre, but undergoes no other change. Neither is it altered by cold water, but at a red heat it decomposes water, and combines with its oxygen, while hydrogen gas is emitted. When heated in an open vessel it gradually combines with oxygen, and evaporates in a white smoke, which, when collected, was formerly called *argentine flowers of antimony*. When suddenly heated, antimony burns, and is converted into the same white oxide. Two oxides of antimony are known.

The protoxide may be obtained thus. Dissolve antimony in muriatic acid, dilute the solution with water; a white powder falls, wash it and boil it in a solution of *carbonate of potash*. Then wash and dry it. The protoxide thus obtained is a dirty white powder. At a moderate red heat, it melts, and becomes opake, and crystallizes in needles on cooling. It is composed of 81.5 antimony, 18.5 oxygen.

The peroxide may be obtained by keeping the antimony in a red heat; for the argentine flowers are peroxide of antimony. It may be obtained also by dissolving antimony in nitric acid, or by throwing it into red hot nitre. It is white, insoluble in water, and less soluble in acids than protoxide. It is easily volatilized by heat, but requires a pretty high temperature for fusion. It is composed of 77 antimony, and 23 oxygen.

Compounds with combustibles.

3. Antimony has never been combined with hydrogen or carbon; but it unites readily to phosphorus and sulphur.

Phosphuret of antimony may be formed by dropping bits of phosphorus into melted antimony. It is white, brittle, and appears of a laminated structure.

Sulphuret of antimony exists native, and was formerly distinguished by the name of *antimony*, the pure metal being called *regulus of antimony*. It has a dark-bluish grey colour, and the metallic lustre. It is brittle, and often crystallized. It is composed of 75 antimony and 25 sulphur.

The protoxide of antimony has the property of dissolving different portions of the sulphuret by means of heat, and forming with it a vitreous substance of a reddish brown colour, and differing in transparency according to the proportion of sulphuret. It is called *glass of antimony, crocus metallorum, liver of antimony*, according to its appearance.

Alloys.

4. Antimony does not combine with the simple incombustibles. But it forms alloys with almost all the metals. It renders other metals brittle, and none of its alloys is of much consequence, except the alloy of tin and antimony, which constitutes *pewter*; and of lead and antimony, which constitutes the metal of printers types.

Sect. XVII. *Of Tellurium.*

Tellurium.

This metal has been hitherto found only in the mine of Mariahilf in Transylvania. Its peculiar nature was first suspected by Muller of Reichenstein in 1782, and fully proved by the experiments of Klaproth in 1798.

Properties

1. Its colour is bluish white, its texture laminated, and its brilliancy considerable. It is very brittle. Its specific gravity is 6.115. It melts a little above the melting point of lead, and may be easily distilled over in close vessels. When cooled slowly it crystallizes.

Oxides.

2. When exposed to the blowpipe on charcoal, it burns with a blue flame, and is converted into a white oxide, which disperses in smoke. The same oxide may be obtained by dissolving the tellurium in muriatic acid, and diluting with water. When heated, it melts into a straw-coloured mass.

3. Tellurium may be combined with sulphur by fusion. The sulphuret has a leaden grey colour and radiated texture. Mr Davy has lately discovered that tellurium combines readily with hydrogen, and forms a gas soluble in water, and possessing, like sulphureted hydrogen, the characters of a weak acid. The action of the other simple combustibles has not been tried.

4. It may be amalgamated with mercury; but we are ignorant of the metallic alloys which it is capable of forming.

Sect. XVIII. *Of Arsenic.*

Arsenic.

The ancients gave the name of *arsenic* to a compound of arsenic and sulphur. The *white oxide of arsenic*, known in commerce by the name of arsenic, must also have been known to them. But they do not seem to have been acquainted with the substance which we call arsenic in its metallic state. The discoverer of this substance is unknown. But Brandt first ascertained its properties, in 1733.

Properties.

1. Arsenic has a bluish white colour, and a good deal of brilliancy. When heated in the open air, it blackens, smokes, and emits the odour of garlic. It is the softest metal known. Its specific gravity is 8.31. It is remarkably brittle. It is very volatile, subliming without melting when heated to 356°. When slowly sublimed, it crystallizes in tetrahedrons.

Oxides.

2. It may be kept under water without alteration, but in the open air it soon falls into a black powder. We know two oxides which it is capable of forming.

The *white oxide* is obtained by exposing arsenic to a moderate heat. The metal takes fire, emits the smell of garlic, and is volatilized in a white smoke, which is the oxide in question. It is obtained in the large way during the smelting of various ores which contain arsenic. It is white, compact, and like glass. Its taste is acrid and sweet, and it is one of the most virulent poisons known. It dissolves in water, and exhibits different properties of an acid. It dissolves also in alcohol, and in oils. It crystallizes in tetrahedrons. It sublimes at the heat of 383°. Its specific gravity varies from 3.7 to 5.000 according to its state. It is composed of 75.2 arsenic, and 24.8 oxygen.

The peroxide of arsenic was discovered by Scheele. It is usually called *arsenic acid*. It may be obtained by dissolving white oxide of arsenic in nitro-muriatic acid, evaporating to dryness, and applying sufficient heat to drive off these acids. In this state it is a white mass, which readily dissolves in water. Its taste is excessively sour, and it possesses all the other properties of an acid. It is composed of 65.4 parts of arsenic and 34.6 of oxygen.

Compounds with combustibles.

3. Arsenic combines readily with the simple combustibles, carbon excepted, with which it has not hitherto been united.

When a mixture of tin and arsenic, or of zinc and arsenic, is dissolved in muriatic acid, the hydrogen which exhales holds a considerable portion of arsenic in solution, and is known by the name of *arsenical hydrogen*. This gas possesses some curious properties, which have been investigated by Trommsdorff and Stromeyer.

Phosphuret of arsenic may be formed by mixing the two constituents, and distilling them together over a moderate fire. It is black and brilliant, and ought to be kept under water.

Sulphur combines readily with arsenic by heat. Two distinct compounds of these two bodies are found native. The first, called *realgar*, is of a scarlet colour, and often crystallizes in transparent prisms. It is tasteless, and not nearly so poisonous as arsenic. It is composed of 60 arsenic and 30 sulphur. The second compound is called *orpiment*. It is of a fine yellow colour, and may be formed by pouring a solution of sulphureted hydrogen into arsenic dissolved in water. It is foliated, and much heavier than realgar. According to Thenard, it is composed of three sulphur and four arsenic.

Alloys.

3. Arsenic does not combine with the simple incombustibles, but it unites with the metals, and renders them brittle. None of its alloys have been applied to any useful purpose.

SECT. XIX. *Of Cobalt.*

Cobalt.

Cobalt occurs in different mines in Germany and England, and has been long employed to give a blue colour to glass. Its peculiar properties were first ascertained by Brandt, in 1733.

Properties.

1. Cobalt has a grey colour, with a shade of red, and is not very brilliant. It is of the hardness of silver, or a little harder. Its specific gravity is 7.7. It is brittle, and easily reduced to powder. It melts at 130° Wedgewood, and crystallizes as it congeals. It is attracted by the magnet, and may itself be converted into a magnet.

Oxides.

2. It is not altered by air nor water at the ordinary temperature of the atmosphere, but in a red heat it is gradually converted into an oxide. We are acquainted with 3 oxides of cobalt.

The protoxide is blue. It may be obtained by dissolving cobalt in nitric acid, precipitating by potash, washing and drying the powder, and exposing it to a red heat for some time. It dissolves in acids without effervescence. It is composed of 83½ cobalt and 16½ oxygen.

Moist protoxide, when exposed to the air, gradually absorbs oxygen, and assumes an olive colour. This is the deutoxide of cobalt. When digested in muriatic acid, oxymuriatic acid flies off, and a solution of protoxide is obtained.

By gradual exposure to the air, more oxygen is absorbed, and the oxide becomes black. This is the peroxide. It forms abundance of oxymuriatic acid gas when digested in muriatic acid. It is composed of 80 cobalt and 20 oxygen.

3. Cobalt does not combine with carbon or hydrogen. Sulphuret of cobalt may be formed by melting the metal with sulphuret of potash. It is yellowish white, and is composed of 71½ cobalt and 28½ sulphur.

Phosphuret of cobalt may be formed, by throwing bits of phosphorus upon red hot cobalt. It is white and brittle, and soon loses its metallic lustre.

4. Cobalt does not combine with the simple incombustibles. It unites with the different metals, and forms alloys which have been but imperfectly examined.

SECT. XX. *Of Manganese.*

Manganese.

Ores of the metal called manganese are common, in which it occurs always in the state of an oxide. Scheele, Bergman, and Gahn, are the chemists to whom we are indebted for the first investigation of its properties. Of late, a valuable set of experiments on it have been made by Dr John of Berlin.

Properties.

1. Manganese, when pure, is of a greyish white colour, similar to cast iron. Its texture is granular. It is brittle, and rather softer than cast iron, as it may be filed. Its specific gravity is 8.013.

Oxides.

2. When exposed to the air, it begins immediately to absorb oxygen, and soon falls to powder. We are acquainted with three oxides of this metal, distinguished from each other by their colours, namely, the *green*, the *brown*, and the *black*. The protoxide, or green oxide, is formed when manganese is thrown into water. The water is decomposed, and the metal assumes the form of a green powder. It is composed of

87 metal.
13 oxygen.

100

The deutoxide, or brown oxide, is formed by exposing the green oxide to the air. It absorbs an additional dose of oxygen, and assumes a brown colour. This oxide is composed of

80 metal.
20 oxygen.

100

The peroxide, or black oxide, occurs native in great abundance. It may be formed artificially, by dissolving manganese in nitric acid, and evaporating to dryness. It is composed of

71.33 metal.
28.67 oxygen.

100.00

3. Manganese does not combine with hydrogen or carbon, but it unites with phosphorus and sulphur.

Phosphuret of manganese may be formed by dropping phosphorus on red hot manganese. It is white, brittle, granular, and disposed to crystallize.

Bergman did not succeed in his attempts to combine sulphur with manganese. But he formed a sulphurated oxide, by heating 8 parts of black oxide and 3 parts of sulphur.

4. Manganese does not combine with the simple incombustibles; but it unites with the metals, and forms alloys which have been but imperfectly examined.

SECT. XXI. *Of Chromium.*

Chromium.

This metal was discovered by Vauquelin, who extracted it from the red lead ore of Siberia. Owing to the violent heat necessary to fuse it, its properties are but imperfectly known.

Properties.

1. Its colour is white, intermediate between that of tin and steel. Its specific gravity is 5.90. It is very brittle, assumes a good polish, and is magnetic,

though inferior in this respect to iron, nickel, and cobalt. Acids act upon it with great difficulty. It requires a very high temperature to melt it, so that hitherto it has only been obtained in small grains.

Oxides.

2. Chromium is not altered by exposure, but when heated in the open air, it is gradually oxidized. Three oxides of this metal are known.

The protoxide, or green oxide, may be obtained by exposing chromic acid to heat in close vessels. Oxygen is disengaged, and the green oxide remains behind.

The deutoxide is intermediate between the green oxide and chromic acid. Its colour is brown.

The peroxide, or chromic acid, is found native in *red lead ore*. It is of a red, or orange colour, soluble in water, and composed of one part chromium and two parts oxygen.

The remaining properties of chromium have not been examined.

SECT. XXII. *Of Uranium.*

Uranium.

This metal was discovered by Klaproth, and extracted by him from an ore which occurs in Saxony, and is known by the name of *pechblende*.

Properties.

1. It requires so violent a heat to melt it, that hitherto the fusion has only been imperfectly accomplished. Its colour is iron grey, it has considerable lustre, and is soft enough to yield to the file. Its specific gravity is 9.000.

Oxides.

2. It forms various oxides, which have been hitherto only examined by Bucholz.

When heated to redness, it undergoes a species of combustion, and is converted into a greyish black powder, which is the protoxide. It is composed of 95 uranium and 5 oxygen.

When uranium is dissolved in nitric acid, and precipitated by potash, it is obtained in the state of a peroxide. It is a yellow, tasteless powder, insoluble in water. It dissolves with effervescence in muriatic acid, oxymuriatic acid gas being exhaled. It is composed of 80 metal and 20 oxygen.

Besides these two oxides, Bucholz is of opinion, that there are several others intermediate between them, distinguishable by their colour. He recognised four, namely, *the violet, the greenish brown, the greyish green, and the orange.*

3. Uranium is capable of uniting with sulphur. No experiments have been made of the action of the other simple combustibles on it. Neither do we know the action of the simple incombustibles, or the alloys which it forms with other metals.

SECT. XXIII. *Of Molybdenum.*

Molybdenum.

This metal is extracted from a scarce mineral called *molybdena*, first examined by Scheele. Molybdenum was first obtained in the metallic state by Hielm.

Properties.

1. Hitherto it has only been obtained in small grains simply agglutinated. Its colour is silvery white. Its specific gravity is 8.611. It is brittle, not altered though kept under water, but the effect of air is unknown.

Oxides.

2. When heated in the open air, it gradually combines with oxygen, and is volatilized in the form of small white needles. It seems capable of forming four different oxides.

The protoxide is brown. It is obtained by exposing molybdenum in powder to a red heat.

By exposing it to a longer and more violent heat, it becomes *violet brown*. This Bucholz considers as a second oxide.

The *blue* oxide may be obtained by carrying the heat a little farther, or by triturating together one part of molybdenum and two parts of molybdic acid, boiling the mass in water, and evaporating the liquid to dryness. This oxide possesses several properties of an acid. It converts vegetable blues to red, and combines with saline bases and forms salts. It may be called *molybdous acid*. It is composed of 100 metal and 34 oxygen.

The *white* oxide, or *molybdic acid*, is obtained by roasting molybdena for some time, dissolving the grey powder in ammonia, and pouring nitric acid into the solution. The oxide precipitates in fine white scales, which, when melted and sublimed, become yellow. It converts vegetable blues to red, but does not act so powerfully as the blue oxide. It is composed of two parts metal and one part oxygen.

3. Molybdenum combines with phosphorus and sulphur, but not with carbon and hydrogen.

Molybdena.

Sulphuret of molybdenum occurs *native*, and is usually called *molybdena*. It is of a bluish grey colour, has the metallic lustre, and is composed of plates. It consists of 60 parts metal and 40 sulphur.

4. The simple incombustibles do not combine with molybdenum; but it unites with the metals, and forms alloys which hitherto have been examined only by Hielm. None of them are of much importance.

SECT. XXIV. *Of Tungsten.*

Tungsten.

Tungsten was discovered by Scheele, and reduced to the metallic state by the D'Elhuyars. It is so difficult of fusion, that hitherto it has been very seldom procured in a tolerably compact state. It is sometimes called *Scheelium*, after the discoverer.

Properties.

1. It is of a greyish white colour, and has a good deal of brilliancy. It is very hard, and seems to be brittle. Its specific gravity is 17.6. It requires a temperature at least equal to 170° Wedgewood to melt it. It is not magnetic.

Oxides.

2. When heated in an open vessel it is gradually oxidized. We are acquainted with two different oxides of this metal, the *blue* and the *yellow*.

The *protoxide*, or *blue* oxide, may be obtained by heating the yellow oxide for some hours in a covered crucible.

The *peroxide*, or *yellow* oxide, may be obtained by boiling tungsten, or its ore, in muriatic acid, decanting off the acid, and allowing it to settle. A yellow powder gradually precipitates. This yellow powder is to be dissolved in ammonia, the solution evaporated to dryness, and the residue kept for some time in a red heat. This yellow oxide is composed of 80 parts metal and 20 oxygen. It combines with bases, forms salts, and therefore has been considered as an acid. Its specific gravity is 6.12.

3. Tungsten combines with sulphur and phosphorus, but not with hydrogen or carbon.

4. The simple incombustibles do not unite with it, but it combines with the metals and forms alloys, hitherto examined only by the Elhuyarts.

Sect. XXV. *Of Titanium.*

Titanium.

This metal was discovered by Mr Gregor; but it received its name from Klaproth, who discovered it without any knowledge of the labours of Gregor.

1. It is so refractory that most persons have failed in their attempts to reduce it. Lampadius is said to have succeeded. Its colour is that of copper, and it has considerable lustre. It is brittle, but elastic.

Oxides.

2. It is easily oxidized by exposure to heat and air. We know three oxides of titanium, the *blue*, the *red*, and the *white*.

The protoxide, which is *blue*, or *purple*, is formed by exposing titanium hot to the open air.

The red oxide is found native. It is often crystallized in four-sided prisms. Its specific gravity is 4.2, and it is hard enough to scratch glass. By a very violent heat it seems to be partially oxidized. It appears to be composed of 100 metal and 33 oxygen.

The *peroxide*, or white oxide, may be obtained by fusing the red oxide in a crucible with four times its weight of potash, and dissolving the whole in water. A white powder gradually precipitates, which is the oxide in question. It is composed of about two parts metal and one oxygen.

3. Titanium has been combined with none of the simple combustibles except phosphorus. The phosphuret is of a white colour, brittle, and granular, and does not melt before the blowpipe.

4. Hitherto titanium has been alloyed with none of the metals, except iron.

Sect. XXVI. *Of Columbium.*

Columbium.

This metal was discovered by Mr Hatchett during the analysis of an ore from America, deposited in the British museum. He obtained from the mineral a white powder, which possessed acid properties peculiar to itself. He shewed that this powder was a metallic oxide; but all attempts to reduce it to the metallic state were unsuccessful. We are at present ignorant of the properties of this metal.

Ekeberg, a Swedish chemist, announced, some years ago, that he had discovered a peculiar metal, to which he gave the name of tantalum. Dr Wollaston has lately proved, that this new metal is the same with Mr Hatchett's columbium.

Sect. XXVII. *Of Cerium.*

Cerium.

This metal was discovered by Hisinger and Berzelius in a mineral found in a Swedish copper mine, and at first confounded with tungsten. To procure the oxide of cerium is easy, but all attempts to reduce that oxide to the metallic state have failed. The metal appears to be volatile, and is dissipated by a violent heat, while a moderate heat is not sufficient to reduce it.

1. Cerium appears to be white and brittle; but its other properties are unknown.

2. It forms, at least, two oxides, the *white* and the *red*; and, according to the Swedish chemists, there are two oxides intermediate between these, the *yellow* and the *brown*.

3. We are unacquainted with the effect of the simple combustibles and incombustibles on cerium. It has been alloyed with iron, but with no other metal.

Sect. XXVIII. *General Remarks.*

General remarks.

The following Table exhibits a synoptical view of some of the principal properties of the metals.

Properties of the metals.

Metals.	*Colour.*	*Hardness.*	*Specific Gravity.*	*Melting Point.*		*Tenacity.*
				Fahrenheit.	*Wedgewood.*	
Gold	Yellow	6.5	19.361		32	150.07
Platinum	White	8	23.000		170	274.31
Silver	White	7	10.510		22	187.13
Mercury	White	0	13.568	—39		
Palladium	White	9	11.871		160+	
Rhodium	White		11.+		160 +	
Iridium	White				160+	
Osmium	Blue				160 +	
Copper	Red	7.5	8.895		27	302.26
Iron	Grey	9	7.8		158	549.25
Nickel	White	8.5	8.820		160+	
Tin	White	6	7.299	442		34.70
Lead	Blue	5.5	11.352	612		27.70
Zinc	White	6.5	6.861	680		109.80
Bismuth	Reddish-white	7.	9.822	476		20.10
Antimony	White	6.5	6.712	810		7.

Titanium	Red				170+	
Columbium					170 +	
Cerium	White				170 +	

Elements of Chemistry.

2. All the metals are capable of combining with oxygen. The knowledge of the number of oxides, and of the proportion of oxygen which they contain, is of great importance. The following Table exhibits a list of these oxides, as far as known, of their colours, and of the quantity of oxygen in each, combined with 100 parts of metal

Table of the oxides.

Metals.	*Oxides.*	*Colours.*	*Oxygen.*
Gold	1 2	Purple Yellow	 32
Platinum	1 2	Green Brown	7.5 15
Silver	1 2	——— Olive	 7.925
Mercury	1 2	Black Red	5 10
Palladium	1 2	Blue Yellow	
Rhodium	P[*]	Yellow	
Iridium	1 2	Blue ? Red ?	
Osmium	P	Transpar.	
Copper	1 2	Red Black	12.5 25
Iron	1 2 3	——— Black Red	 29.5 44.25
Nickel	1 2	Grey Black	28
Tin	1 2 3	——— Grey White	— 25 38.8
Lead	1 2 3	Yellow Red Brown	7.7 11.1 15.4
Zinc	1	White	24.4
Bismuth	P	Yellow	12
Antimony	1 2	White White	22.7 30
Tellurium	P	White	
Arsenic	1 2	White Acid	33 53
Cobalt	1 2 3	Blue Green Black	19.7 25
Manganese	1 2 3	Green Brown Black	15 25 40.
Chromium	1 2 3	Green Brown Red	 200
Uranium	1 2	Black Yellow	5.17 28
Molybdenum	1 2 3 4	Brown Violet Blue White	 34 50
Tungsten	1 2	Black Yellow	15 25
Titanium	1 2 3	Blue Red White	16 33 49
Columbium	P	White	
Cerium	1 2	White Red	

3. Of the simple combustibles, *carbon* has been only united hitherto to two metals, namely *iron* and *nickel:* hydrogen gas dissolves arsenic, zinc, and iron, seemingly in the metallic state: phosphorus combines with most of the metals hitherto tried; but these compounds have been applied to no useful purpose: sulphur likewise combines with most metals; the sulphurets are often found native; some of them are prepared artificially, as paints: we do not knowthe action of boracium on the metals.

4. The action of the simple incombustibles on metals is not striking.

5. The combinations of the metals with each other, called *alloys*, are some of them, as those of zinc and tin, of great importance. The greater number of them have only been very superficially examined.

DIVISION II.

Of Unconfinable Bodies.

Unconfinable bodies.

The unconfinable bodies cannot be examined directly; because we have no method of retaining them till we ascertain their properties. We can only draw inferences respecting them, by seeing the changes produced upon those bodies into which they enter, or from which they separate. They are four in number, namely, *light*, *heat*, *electricity*, and *magnetism*. But the examination of the two last is not considered as the province of chemistry. The two first will occupy our attention in the following Chapters.

Chap. I.

Of Light.

Light.

Every person is acquainted with the light of the sun, and of burning bodies, and that it is by means of light that bodies are rendered visible.

Huygens considered light as a subtile fluid filling space, and rendering bodies visible by the undulations into which it is thrown. While Newton, and almost all other philosophers, consider it as a subtile substance, constantly separating from luminous bodies, moving in straight lines, and rendering bodies visible by entering the eye.

Motion of light.

Light takes about 8 minutes in moving across half the earth's orbit, which is a space exceeding 94 millions of miles; of course its velocity is not much less than 200,000 miles in a second. From this velocity, joined to the imperceptible effect produced by the impulse of the particles of light on other bodies, it is obvious that its particles are inconceivably minute. Hence the reason that they produce no perceptible effect upon the most delicate balance.

Refraction.

While a ray of light moves in the same medium, or when it passes perpendicularly from one medium to another, it does not change its direction. But when it passes obliquely from one medium to another, it changes its direction, and is then said to be *refracted.* When it passes from a rarer to a denser medium, it is refracted *towards* the perpendicular; when from a denser to a rarer, it is refracted *from* the perpendicular. In the same medium, the sines of the angles of incidence and refraction have a constant ratio.

Reflection.

When a ray of light strikes obliquely against a plane surface, even though transparent, instead of passing through, it is bent back in a contrary direction. Just as would happen if an elastic ball were made to strike obliquely against the ground. The ray is then said to be *reflected.* The angle of reflection is always equal to the angle of incidence.

When a ray of light passes within a certain distance of another body, it is bent *towards* it; at a different distance it is bent *from* it. In the first case, the ray is said to be *inflected*, in the second to be *deflected*.

---

[*] The letter P in the second column signifies *Peroxide.*

Light composed of seven rays.

When a ray of light is made to pass through a triangular glass prism, and received upon a sheet of paper, the image or *spectrum*, as it is called, instead of being round, is oblong. This spectrum exhibits seven different colours, in the following order, beginning with the lowest; *red, orange, yellow, green, blue, indigo, violet*. In this case the refraction of the ray is increased by the figure of the prism; and if it be heterogeneous, and consist of rays differing in refrangibility, they will separate from each other, the most refrangible going to the top of the spectrum, the least refrangible to the bottom, and the others in their order. This is the case. Light consists of seven different rays, distinguished by seven different colours. The *red* is the *least* refrangible, and the *violet* the *most*. The refrangibility of the rest is in the order of their names.

The rays of light differ in their power of illuminating objects. The lightest green or deepest yellow gives the most light, and the light diminishes as we approach either extremity of the spectrum. The violet has the least illuminating power.

Exists in bodies.

Light is capable of entering into bodies and remaining in them, and of afterwards being extricated by various means. Such bodies are said to *phosphoresce*. Almost all bodies possess this property to a certain extent. If they be exposed to the sun, and suddenly carried to the dark, they are luminous for some time, but in general for a very short period. Some bodies seem to contain light as a constituent, from which it may be extricated by various means. Thus fluor spar, and various other minerals, become luminous when heated. Herring, other fish, meat, and wood, often become luminous just before they begin to putrefy, and often continue luminous for a considerable time.

Produces changes on bodies.

Light produces considerable changes upon certain bodies. The *green colour* of plants is owing to it; for when they vegetate in the dark, they are white. Nitric acid is decomposed by exposure to the light, and oxygen gas emitted. The oxide of silver, and perhaps also of gold, is reduced by exposure to light. Till lately, it was supposed that these changes were produced by the colorific rays of light. But it has been recently ascertained, that muriate of silver is blackened most rapidly when placed beyond the violet ray, and entirely out of the prismatic spectrum. Hence it follows, that the change is produced, not merely by the colorific rays, but by rays which are incapable of rendering objects visible, or of producing any sensible heat. Thus we learn that the solar light contains at least two distinct sets of rays, one set which renders bodies visible, and another which blackens muriate of silver, and reduces metallic oxides. This second set may be called *deoxidizing* rays, till some better name is thought of. They are obviously more refrangible than the colorific rays.

Such are the properties of light. They are sufficient to induce us to believe that it is a *body*; but it possesses three peculiarities, by which it is distinguished from all the substances hitherto described. It has the power of exciting in us the sensation of vision; it always moves with a prodigious velocity, and the particles of it are never found cohering together in masses. This last property cannot well be accounted for, unless we suppose that its particles *repel* each other.

Sources.

The sources of light are, the *sun* and *stars*, *combustion*, *heat*, and *percussion*.

The light emitted by the sun is familiarly known by the name of the *light of day*. In all cases of rapid combustion light is emitted: but different substances vary very much in the quantity of light which they give out while burning. All substances, except *gases*, become luminous when heated to a certain temperature (about 700°). They are then said to be red hot. When hard substances, as two quartz stones, flint and steel, are struck against each other, luminous sparks are emitted. This is sometimes, (as in the case of flint and steel) owing to the particles given off catching fire; but in other cases, the appearance of the spark has not been accounted for.

CHAP. II.

Of Caloric.

Caloric.

THE meaning of the word *heat* is so well understood, that any attempt to define it is unnecessary. When we say that *a person feels heat*, that *a stone is hot*, the expressions are understood readily. Yet in each of these propositions, the word *heat* has a distinct meaning. In the first it signifies the *sensation of heat;* in the second, the *cause* of that sensation. to avoid the supposed ambiguity of these two meanings to one word, the term *caloric* was invented to signify the *cause of heat*. When I put my hand on a hot stone, I experience a certain sensation, which I call the *sensation of heat*; the *cause* of this sensation is *caloric*. The phenomena of heat, which are of the utmost importance in chemistry, will be treated of in the following sections.

SECT. I. *Of the Nature of Caloric.*

Nature of caloric.

Two opinions respecting the nature of caloric have divided philosophers. According to some, like *gravity*, it is merely a property of matter, while others consider it as a peculiar substance. The latter opinion was first broached by the chemists, and is at present acceded to by almost the whole body of philosophers. A recent discovery of Dr Herschel has rendered this opinion, if possible, still more plausible than before.

Rays of heat.

Dr Herschel, while employed in examining the sun by means of telescopes, thought of examining the heating power of the different rays separated by the prism. He found that the most refrangible rays have the least heating power, and that the heating power gradually increases as the refrangibility diminishes. The *violet* ray of course has the least, and the *red* ray the greatest heating power. It struck Dr Herschel as remarkable, that the illuminating power and heating power follow different laws. The illuminating power is greatest in the middle of the spectrum, but the heating power is greatest at the *red* end. This led him to suspect, that the heating power does not stop at the end of the spectrum. On trying the experiment, he found that a thermometer placed a little beyond the spectrum rose still higher than when in the red ray. This important experiment was successfully repeated by Sir Henry Englefield. Hence it follows, that there are rays emitted from the sun which produce heat, but have not the power of illuminating: consequently caloric is emitted from the sun in rays, and the rays of caloric are not the same with the rays of light.

All the illuminating rays have the power of exciting heat. It is probable that they derive this power from rays of caloric mixed with them; for the rays from the moon, though they consist of the seven prismatic rays, do not, even when concentrated, affect the most delicate thermometer.

Thus it appears that solar light is composed of three sets of rays, the *colorific*, the *calorific*, and the *de-oxidizing*.

The rays of caloric are refracted and reflected precisely as the rays of light. They obviously move with a very considerable velocity, though what that velocity is we do not at present know. It has been ascertained that caloric produces no sensible effect upon the weight of bodies; the weight remaining sensibly the same, whether a substance be hot or cold. In this respect it agrees with light. It agrees with light also in another property, its particles are never found cohering together in masses.

SECT. II. *Of the Motion of Caloric.*

Of the motion of caloric.

When heat radiates from the surfaces of bodies, it moves with great velocity; but, when it makes its way through bodies, it moves comparatively slowly. Let us consider these two kinds of motions.

1. *Escape of Heat from Surfaces.*

Escape of heat from surfaces.

When bodies, artificially heated, are exposed to the open air, they emit heat, and continue to do so till they sink to the temperature of the surrounding atmosphere. The rapidity of their cooling depends upon the nature of their surface. For the investigation of this branch of the subject, we are indebted chiefly to the sagacity of Professor Leslie. A globe of bright tin, filled with hot water, lost a certain number of degrees of heat in 156 minutes. But, when covered with a thin coat of lamp-black, it lost the same number of degrees in 81 minutes. The rate of cooling was likewise increased by covering it over with a coat of linen, and by painting it with black or white paint. This difference is only conspicuous in still air. In a strong wind it diminishes, or nearly disappears.

Leslie's experiments.

When a canister of tin, filled with hot water, is placed before a concave mirror of bright polished tin, having a delicate thermometer in the focus, the thermometer experiences a certain elevation. The *differential* thermometer, invented by Mr Leslie, answers best for these experiments. It consists of a small glass tube, bent into the shape of the letter U, and terminating at each extremity in a small hollow ball. The tube is filled with sulphuric acid, tinged red with carmine. An ivory scale is affixed to one of the legs, and the top of the liquid stands at the division of the scale marked 0. This thermometer is not affected by any change in the temperature of the room. But if one of its balls be heated, while the other is not affected, the air within it expands and pushes away the sulphuric acid, which rises in the other leg. Hence it indicates changes of heat in a particular point, as the focus of a mirror. The ball of it which is applied to the point, and undergoes the change, is called the *focal ball*.

When the experiment is made in the way above specified, the rise of the thermometer depends upon the distance of the canister from the mirror, being always the greater the nearer the canister is to the mirror. From Mr Leslie's experiments it follows, that the effect on the thermometer is very nearly inversely proportional to the distance of the canister from the reflector.

When the nature and position of the canister is the same, the rise of the thermometer is always proportional to the difference between the temperature of the hot canister and that of the surrounding air.

Heat radiates from the surfaces of hot bodies in all directions, but the radiation is most copious in the direction perpendicular to the surface of the hot body.

When different bodies are applied in succession to the surface of the canister, their power of radiation becomes evident, by the effect they produce upon the thermometer. The following Table exhibits this effect, as ascertained by the experiments of Mr Leslie.

Radiating power of bodies.

Lamp-black,	100°
Water, by estimate,	100+
Writing paper,	98
Rosin,	96
Sealing wax,	95
Crown glass,	90
China ink,	88
Ice,	85
Minium,	80
Isinglass,	80
Plumbago,	75
Tarnished lead,	45
Mercury,	20+
Clean lead,	19
Polished iron,	15
Tin-plate,	12
Gold, silver, copper,	12

Thus it appears that metals radiate heat worst, and that lamp-black, paper, and glass, are among the best radiators of it tried. The radiating power of the metals is increased by tarnishing and by scratching their surface.

The radiating powers of these bodies were ascertained by applying thin coats of them to the surface of the canisters. Now, it appears that the radiating power increases somewhat with the thickness of the coat, till that coat amounts to the $\frac{1}{1000}$ of an inch, when it remains stationary. But this does not hold with respect to metallic bodies, the thinnest coat of which produces as great an effect as the thickest.

When the focal ball of the thermometer is glass, let us suppose that it rises 100°. If we coat it with tin-foil, the rise will be reduced to 20°. Hence it follows, that those bodies that radiate heat best imbibe it best, and that those which radiate worst imbibe worst.

The contrary holds with respect to reflectors; those substances reflect *best* which radiate *worst*, and *vice versa*. The following Table exhibits the comparative goodness of different substances as reflectors, according to Mr Leslie's experiments.

Reflecting power.

Brass,	100
Silver,	90
Tin-foil,	85
Block-tin,	80
Steel,	70
Lead,	60
Tin-foil, softened by mercury,	10
Glass,	10
Ditto, coated with wax or oil,	5

When the polish of the reflector is destroyed by rubbing it with sand paper, the effect is very much diminished.

Radiation takes place only in elastic mediums. It is destroyed altogether by plunging the apparatus under water. It is nearly the same in air and in hydrogen gas, and does not seem to be affected by the nature of the elastic medium. It is diminished by rarefying the surrounding air.

Effect of a screen.

When a substance is interposed between the hot canister and the reflector by way of screen, the effect is varied by its distance from the canister, by its thickness, and by the nature of its surface. The nearer it is to the canister, the less is the radiation affected; at a certain distance all radiation is destroyed. The thinner the screen, the less of the heat is interrupted; the radiation slowly diminishes as the thickness of the screen increases. When the surface of the screen radiates heat well, the radiation is much less interrupted than if it radiate heat ill. Thus, if the screen be glass, the thermometer still rises a certain number of degrees, but if it be tin-foil the thermometer does not rise at all. From these phenomena it cannot be doubted that the screen, in all cases, intercepts the whole of the heat, that it becomes hotter itself, and then radiates heat from its surface.

Such are the phenomena of the radiation of heat as far as they have been investigated. It follows very different laws from light in its radiation. Mr Leslie has endeavoured to show, that heat is not in reality radiated, but that it is propagated with the velocity of sound by means of undulations or pulses of air. This opinion he has supported with much ingenuity. But as he has brought no other evidence for its truth, but its convenience in explaining the phenomena, and as it is at variance with the direct experiments of other philosophers, it cannot be admitted till direct evidence be brought forward in support of it.

2. *Passage of Caloric through Bodies.*

Passage of caloric through bodies.

Caloric, we have seen, is incapable of radiating through solid bodies, yet it is well known that all bodies are pervious to it. Through them, then, it must make its way in a different manner. In general it passes very slowly through them, and when it passes in this way, it is said to be conducted through them.

Bodies seem to conduct heat in consequence of their affinity for it, and of the property which they have of combining with an indefinite number of doses of it. Hence the reason of the slowness of the process. Hence also the reason why the temperature of the body through which it passes diminishes equally as we advance from the source of heat to the other extremity.

Conducting power of bodies.

Bodies vary in their power of conducting heat. The metals are the best conductors of heat of all known bodies. From the experiments of Ingenhousz it follows, that silver and gold are the best conductors among the metals. Copper and tin follow next in order, and platinum, iron, steel, and lead are nearly equal among themselves, but much inferior to the others. Stones come next after the metals, but they are greatly inferior to them. Bricks are still inferior to stones. Glass also is a bad conductor. Hence the facility with which it cracks when suddenly heated or cooled.

Dried woods are considerably inferior to glass. From the experiments of Meyer, it appears that they differ considerably among themselves. Charcoal is also a bad conductor. According to the experiments of Morveau, its conducting power is to that of fine sand as 2 to 3. Feathers, silk, wool, and hair are still worse conductors than any of the preceding substances. Hence the reason that they answer so well as articles of clothing.

It is admitted on all hands, that all solid bodies are conductors, for they allow heat to pass through them. Liquids also allow heat to pass through them. But they differ from solids in the mobility of their particles. When a particle of a liquid is heated, it becomes specifically lighter, and therefore rises. Count Rumford has endeavoured to prove, that heat passes through liquids only in consequence of the motion of their particles, and that if the particles of liquids were immoveable, heat could not pass through them at all. Hence he infers, that liquids are, in reality, non-conductors of caloric. But his experiments are not such as to warrant the conclusions he has drawn. The subject has been investigated by different chemists, with all the requisite care. It has been shown that heat can make its way downwards through liquids, in which case their particles cannot be supposed to move. Hence it follows, that they are all conductors. They are, however, very bad conductors. Water, for example, conducts heat much worse than any of the dry woods.

The gases are still worse conductors than liquids. They differ a good deal among themselves in their conducting power. Hydrogen gas appears to be the best, and carbonic acid the worst conductor. From the experiments of Leslie, it appears, that hydrogen conducts four times as well as common air. The conducting power of gases is diminished by rarefaction, by vapours of all kinds, and every thing which has a tendency to dilate air. The following Table by Mr Dalton, exhibiting the time taken by a thermometer to cool a given number of degrees in the different gases, will give the reader some idea of their relative conducting powers.

Rate of cooling in gases.

	Seconds.
Carbonic acid, ...	112
Sulphureted hydrogen,	100+
Nitrous oxide, ...	
Olefiant gas, ...	
Common air, ...	100
Oxygen, ...	
Azotic gas, ...	
Nitrous gas, ...	90
Gas from pitcoal, ...	70
Hydrogen gas, ...	40

SECT. III. *Of the equal Distribution of Temperature.*

Of the equal distribution of temperature.

When substances of different temperatures are placed in each other's neighbourhood, the hotter bodies become colder, and the colder acquire heat, and the changes continue till all the bodies acquire the same temperature. This property of caloric of distributing itself equally, has been called the *equilibrium of caloric.* It might with more propriety be called the *equal distribution of temperature.*

It had been taken for granted by Sir Isaac Newton, and was proved by the experiments of Krafft and Richmann, that when a body is suspended in a medium of a temperature different from its own, the difference between the temperature of the body and the medium diminishes in a geometrical ratio, while the time increases in an arithmetical ratio; or, which comes to the same thing, that in given small times, the heat lost is always proportional to the heat remaining in the body.

SECT. IV. *Of the Effects of Caloric.*

Of the effects of caloric.

The changes which caloric produces on bodies may be arranged under three different heads; namely, 1. Changes in bulk; 2. Changes in state; and 3. Changes in combination.

1. *Changes in Bulk.*

Changes in bulk.

Every addition or abstraction of heat produces a corresponding change in the bulk of the body affected. In general, the *addition* of heat produces *expansion*, and the *abstraction* of it produces a *diminution* of bulk. To this general law there are perhaps one or two exceptions.

Expansion

The expansion of gases by heat is greatest, that of liquids much smaller, and that of solids smallest of all. Thus, 100 cubic inches of air by being heated from 32° to 212°, expand to 137.5 inches. The same augmentation of temperature makes 100 cubic inches of iron, by the same increase of temperature, expand only to 100.1 inches.

of gases.

All gases undergo the same expansion by the same augmentation of temperature, and the same contraction by the same diminution of temperature. This change is nearly equable, though it is a little less at high temperatures than at low. From the most exact experiments hitherto made, we may conclude, that air and all gases expand about $\frac{1}{481}$ part of their bulk for every degree of heat thrown into them.

From the experiments of Gay-Lussac, it appears that the steam of water and the vapour of ether undergo the same dilation as air, when the same addition is made to their temperature. Hence it is reasonable to conclude, that all elastic fluids expand equally and uniformly by heat.

Liquids.

The expansion of liquids differs from that of elastic fluids, not only in quantity, but in the want of uniformity. Every liquid has a peculiar expansion of its own, different from that of every other liquid. The expansibility is greater when the temperature is high, than when it is low. Alcohol expands most of all the liquids hitherto tried; 100,000 parts of it at 32°, become 104,162 at 100°. Nitric acid is the next in order, then lintseed oil, then oil of turpentine, then sulphuric acid, then water, and mercury is the least expansible of all the liquids hitherto tried.

Solids.

The solids expand much less than the liquids. As far as observation has gone, their expansion is equable, or at least their deviation from it is insensible. 100,000 parts of glass at 32°, become at 100,083 at 212°. The order of the expansibility of the principal metals is as follows, beginning with the least expansible. Platinum, gold, antimony, cast-iron, steel, iron, bismuth, copper, brass, silver, brass-wire, tin, lead, zinc.

Thermometer.

The property which bodies have of expanding when heat is applied to them, has suggested an instrument for measuring the relative temperatures of bodies. This instrument is the *thermometer.* A thermometer is a hollow tube of glass hermetically sealed, and blown at one end into a hollow globe or *bulb.* The bulb and part of the tube are filled with mercury. When the bulb is plunged into a hot body, the mercury expands, and of course rises in the tube; when it is plunged into a cold body, the mercury contracts, and of consequence sinks in the tube. Thermometers are made in this way. The requisite quantity of mercury being introduced, the thermometer is plunged into melting snow, and the place where the mercury stands is marked. This is called the *freezing point.* The thermometer is then plunged into boiling water, and the point at which the mercury stands marked. This is called the *boiling water point.* The distance between these two points is divided into a number of equal parts called degrees, and these degrees are continued indefinitely above and below these two points.

The thermometer gets its name according to the number of degrees into which the space between the freezing and the boiling point is divided. There are four thermometers still used in Europe. In that of Reaumur, the space between the two points is divided into 80°. The freezing point is marked 0, the boiling point 80°. In the thermometer of Celsius, the same space is divided into 100°. The freezing point is marked 0, the boiling point 100°. This is the thermometer used in Sweden and in France since the revolution. In the thermometer of Fahrenheit, the space between the two points is divided into 180°. But the scale begins at the cold produced by a mixture of snow and salt, which is 32° below the freezing point. The freezing point is marked in consequence 32°, and the boiling point 212°. This is the thermometer used in Britain. It is the one always used in this article, except when some other is expressly mentioned. In the thermometer of Delisle, the space between the two points is divided into 150°, but the graduation begins at the boiling point, which is marked 0. The freezing point is marked 150.

As mercury does not expand equably, the thermometer does not give us an exact measure of the increase of heat. Mr Dalton has endeavoured to prove that mercury expands as the square of the temperature, reckoning from its freezing point. This opinion has induced him to construct a new thermometer, graduated according to that principle. If this opinion be correct, the common degrees are too large near the bottom of the scale, and too small towards the upper part of it. 122°, or half way between freezing and boiling, corresponds according to the new graduation with 110° of the old.

Exceptions to expansion:

The exceptions to expansion by heat are of two kinds. 1. Those liquids which have a maximum of density corresponding with a certain temperature, and which of consequence expand whether they be heated or cooled beyond that temperature.

2. Certain liquids which become solid by cooling, and expand during the solidification.

1. Water.

Water is the only liquid at present known belonging to the first class. Its greatest density is at the temperature of 40°, or a little below it. If it be heated above that temperature it expands, and it expands equally if it be cooled below it. A vast number of experiments have been made upon this point, and there appears no doubt of the matter of fact. Mr Dalton has lately endeavoured to show, that 36° is the degree at which the density of water is a maximum, and his observations appear satisfactory. No satisfactory explanation of the cause of this singular anomaly has yet been offered.

2. Other bodies.

The second class of bodies is numerous. Water expands with great force when it freezes, and is converted into ice. The specific gravity of ice is 0.92, that of water at 60° being 1.00. Hence, ice is lighter than even boiling hot water. It always, therefore, swims on the surface of the water. A similar expansion is observable during the crystallization of most of the salts. Among the metals there are three which expand in the act of congealing; these are *cast-iron*, *bismuth*, and *antimony*. All the rest seem to contract instead of expanding. Sulphur appears also to expand when it congeals. This expansion in these bodies must be ascribed to a new arrangement, which their integrant particles assume. It would lead one to suppose a kind of polarity in these integrant particles, otherwise it is difficult to conceive why they tend to expansion with so much force. Honey, oils, and most metals contract when they become solid. Sulphuric acid also appears to contract.

2. *Changes in the State of Bodies.*

Changes in the state of bodies.

All substances in nature, as far as we know them, occur in one or other of the three states, that of *solids*, of *liquids*, and of *elastic fluids*. In a vast number of cases, the same substance is capable of assuming each of these states in succession. Thus sulphur is usually solid, but at 218° it becomes a liquid, and at 570° it boils, and is converted into an elastic fluid. Water is a liquid, but at 32° it freezes into a solid, and at 212° it boils into an elastic fluid.

All solids (a very few excepted) may be converted into liquids, by heating them sufficiently; and almost all liquids, by cooling them sufficiently, may be converted into solids. The law then is, that solids by heat are converted into liquids and elastic fluids; while elastic fluids and liquids by cold are brought into the state of solids.

Freezing explained.

1. When solids are converted into liquids, the change in some cases takes place at once, without any perceptible interval between solidity and liquidity. In other cases, the solid passes slowly through all the intermediate degrees of softness, till at last it becomes a complete liquid. The melting of ice is an example of the first kind, that of wax and tallow of the second. This change takes place at a particular temperature, which is easily ascertained in the first class, but not so easily in the second. If the substance at the usual temperature of the atmosphere be liquid, this point is called the *freezing point*; but if it be usually solid, it is called the *melting point*.—Thus 32° is the *freezing point* of water, and 476° the *melting point* of bismuth.

Freezing of water.

Though 32° be the freezing point of water, it may be cooled down considerably below that point without freezing. In thermometer tubes, we have cooled it down to 7°, and in a wine glass to 20°. When agitated or touched with a bit of ice, it freezes very suddenly.

The freezing point of water is lowered by dissolving different salts in it. Thus water saturated with common salt freezes at 4°, with sal ammoniac at 8°, with Rochelle salt at 21°, and with nitre at 26°. When the proportion of the same salt dissolved in water is varied, it follows from the experiments of Sir Charles Blagden, that the freezing point is always proportional to the quantity of the salt.

Of acids.

The nitric and sulphuric acids vary remarkably in their freezing points, according to circumstances. When much diluted with water, the weakest part freezes, while a strong portion remains liquid. When very much diluted, the whole freezes, and the freezing point is lower according to the proportion of acid present. The strong acids themselves undergo congelation, and each has a particular strength at which its congelation is the easiest. If it be stronger or weaker, more cold is necessary to congeal it. Sulphuric acid of the specific gravity 1.780 freezes at 46°. But if it be diluted with a little water, it requires a cold of —45°; the strongest sulphuric acid freezes at 1°. The strongest nitric acid freezes at —45.5°. When considerably weaker it freezes at —2°, and when still weaker at —27.7°.

Latent heat.

We are indebted to Dr Black for the first satisfactory explanation of the change of solids into liquids by heat. According to him, solids, in order to liquify, combine with a quantity of heat which enters into them, and remains in them without increasing their temperature. Hence he called it *latent heat*. Liquids congeal by giving out this *latent heat*. This opinion is established by simple but satisfactory experiments, and he ascertained that the latent heat of water is 140°. The following Table exhibits the latent heat of some other liquids, as ascertained by the experiments of Dr Irvine :

	Latent heat.	Ditto reduced to the specific heat of water.
Sulphur . .	143.68	27.14
Spermaceti .	145	
Lead	162	5.6
Bees wax . .	175	
Zinc	493	48.3
Tin	500	33
Bismuth . .	550	23.25

Dr Black has shewn also, that the softness of such bodies as are rendered plastic by heat, depends upon their combining with a quantity of caloric.

2. Thus the conversion of solids into liquids is owing to their combining with heat. There is another change no less remarkable, to which bodies are liable when exposed to the action of heat. Almost all liquids, when exposed to a certain temperature, gradually assume the form of an elastic fluid, possessing the properties of air. These fluids retain their elastic form as long as the temperature continues, but when cooled down they lose that form, and are converted into liquids.

Evaporation.

Some liquids are gradually converted into elastic fluids at all temperatures, while others do not begin to undergo the change till heated to a certain temperature. Water and alcohol are well known examples of the first class of liquids ; sulphuric acid, and the fixed oils, of the second. Water gradually evaporates, even when in the state of ice, but sulphuric acid not till heated above 212°. The first class of liquids are said to *evaporate* spontaneously.

When other circumstances are the same, the evaporation increases with the temperature, and the elasticity of the vapour, of course, increases in the same proportion. At a certain temperature this elasticity balances the pressure of the atmosphere. When that happens, if the heat be applied below, the liquid assumes the aërial form with great rapidity. The vapour forces its way through the liquid, and a violent agitation is the consequence. The liquid is then said to *boil*. Every particular liquid has a certain temperature at which it begins to boil. Thus, ether boils at 98°, alcohol at 174°, and water at 212°.

Boiling.

The boiling point varies with the pressure of the atmosphere. It is highest when the barometer is high, and lowest when it is low. All liquids boil in a vacuum about 145° lower than under the pressure of the atmosphere. The elasticity of vapour increases with the temperature. At 32° the vapour of water is capable of supporting a column of mercury 0.2 inches high ; at 212° it supports a column of 30 inches.

Dr Black applied his theory of latent heat to the conversion of liquids into elastic fluids, and showed that it is owing to the very same cause as the conversion of solids into liquids, namely, to the combination of a certain dose of caloric with the liquid without any increase of temperature. From his experiments, compared with those of Mr Watt and Mr Lavoisier, it appears that the latent heat of steam is about 1000°.

Thus it appears that Dr Black's law is very general, and comprehends every change in the state of a body. It may be stated in its most general form as follows. *Whenever a body changes its state, it either combines with caloric, or separates from caloric.*

3. It is probable, that all elastic fluids, or gases, owe their elastic form, like steam, to the combined caloric which they contain ; and that, if they could be subjected to a sufficient degree of cold, they would lose their elasticity, and be converted into liquids or solids. This has been done successfully to some gases ; oxymuriatic acid and ammonia, for example, become liquid, when cooled down low enough. The experiment has not succeeded with other gases, even though subjected at once to cold and pressure.

3. *Changes in Composition.*

Changes in composition.

Caloric not only increases the bulk of bodies and changes their state, but its action decomposes many compounds altogether, either into their elements, or it causes these elements to combine in a different manner. Thus, ammonia, in a red heat, is resolved into hydrogen and azotic gases ; and alcohol, by the same heat, is converted into inflammable air and water.

In general, those compounds, which have been formed by combustion, resist the action of heat with considerable obstinacy. Those that contain oxygen, and which have been formed without combustion, are easily decomposed, and so are most of those that contain combustibles.

Sect. V. *Of the Quantity of Caloric in Bodies.*

Of the quantity of caloric in bodies.

This investigation naturally divides itself into two parts : 1. The *relative quantities* of heat in bodies, or the quantities in each necessary to produce a given change of temperature. This is usually termed *specific caloric*. 2. The *absolute quantity* of heat which exists in bodies.

1. *Of the Specific Caloric of Bodies.*

Specific heat explained.

If equal weights of water and spermaceti oil be mixed at different temperatures, it is natural to expect that the mixture will acquire the mean temperature. Suppose the temperature of the water 100°, and that of the oil 50°, it is reasonable to expect that the water would be cooled down 25°, and that the oil would be heated 25°, and that the temperature after mixture would be 75°. But, if we make the experiment, we find the result very different. The temperature, after mixture, instead of 75°, is 83⅓°, consequently the water has lost only 16⅔, while the oil has gained 33⅓. If we mix together equal weights of water at 50°, and spermaceti oil at 100°, the temperature, after agitation, will be only 66⅓°, so that the oil has lost 33⅓, while the water has only gained 16⅔. This experiment demonstrates that the same quantity of heat does not produce the same effect on water and spermaceti oil. The quantity which raises water 16⅔, raises the oil 33⅓, or it produces double the effect upon the oil that it does on the water. If the other substances be tried in the same manner, we shall find that they all differ from each other in the quantity of caloric necessary to heat each of them a given number of degrees, some requiring more than the same weight of water would do, and others less. Now, the quantity necessary to produce this effect is called the *specific caloric* of each. The specific caloric of water is taken as the standard and called 1, and all the others referred to it. It is obvious, from the preceding example, that the specific caloric of water is double that of spermaceti oil. If we represent the first by 1, we must, of course, represent the second by 0.5.

This investigation was begun by Dr Black, and prosecuted by Dr Irvine and Dr Crawford, who published a table of the specific heat of various bodies, and made it the foundation of his explanation of animal heat. Mr Wilcke of Sweden likewise investigated the specific heat of various bodies. Lavoisier and Laplace attempted the investigation, by ascertaining how much ice given weights of bodies, heated a certain number of degrees, was capable of melting during the cooling. The subject was afterwards prosecuted by Kirwan, Meyer, Leslie, and Dalton. The following Table exhibits the result of all the experiments hitherto published on this important subject.

Table of the specific heats of bodies.

The specific heats of the gaseous bodies in the preceding table were ascertained by Dr Crawford, by means of very delicate experiments, made with every possible precaution to insure accuracy. Yet there is little probability that they are accurate. Nor are we in possession of any means of making them more so by experiment. Mr Dalton has calculated the specific heat of the different gases from theory. The following are the numbers he obtained. The specific heat of water, as usual, being 1.

Hydrogen gas	9.382
Azotic	1.866
Oxygen	1.333
Air	1.759
Nitrous gas	0.777

Nitrous oxide	0.549
Carbonic acid	0.491
Ammonia	1.555
Carbureted hydrogen	1.333
Olefiant gas	1.555
Nitric acid	0.491
Carbonic oxide	0.777
Sulphureted hydrogen	0.583
Muriatic acid	0.424
Aqueous vapour	1.166
Ether vapour	0.848
Alcohol vapour	0.586

Dr Crawford supposed, that the specific heat of bodies is permanent while they retain their state. But Mr Dalton has lately endeavoured to prove, that it increases with the temperature of all bodies.

Dr Irvine ascertained, that the specific caloric always changes with the state of a body. When a solid becomes a liquid, or a liquid an elastic fluid, the specific caloric increases. When an elastic fluid becomes a liquid, or a liquid a solid, the specific heat diminishes.

The specific heat of bodies is increased by combining them with oxygen. Thus, the specific heat of metallic oxides is greater than that of metals, and of acids than of their bases.

2. *Of the Absolute Quantity of Caloric in Bodies.*

As the same quantity of heat produces different changes of temperature in different bodies, it is obvious, that the thermometer cannot indicate the absolute quantity of heat in bodies. Now, it becomes a question of considerable importance to inquire, if there be any method of ascertaining the absolute quantity of heat in bodies. Supposing a body deprived of all heat, and a thermometer applied to it, at what point would the thermometer stand?

Absolute heat, how ascertained.

Dr Irvine is the philosopher who first attempted to solve this problem. His reasoning was founded upon two suppositions. 1. That the specific heat was proportional to the absolute heat of bodies. 2. That the heat emitted or absorbed by a body, when it changes its state, is merely the consequence of the change which has taken place in its specific heat. Thus, when ice is converted into water, 140° of heat are absorbed; because the specific heat of water is so much greater than that of ice, that 140° are necessary to maintain the temperature. The first of these two suppositions gave him the ratio of the absolute quantity of heat in bodies, and the second, the difference between two absolute calorics. Thus, if the specific heat of water be 10, and that of ice 9, then the absolute quantity of heat in water is, to that in ice, as 10 to 9. Call the absolute heat of ice x, then that of water is $x+140$, and we have $x : x+140 :: 9 : 10$. Hence we get this equation, $10x = 9x+1260$, which gives us $x=1260$. Water at 32° of course contains 1400° of caloric. Dr Crawford, from his experiments, stated the real zero at 1500 below 0; and Mr Dalton places it at 6000 below 0.

Unfortunately, the truth of the two suppositions upon which this ingenious reasoning is founded, cannot be admitted. We have no proof that the specific heat of bodies is proportional to their absolute heat. The second supposition is at variance with the mechanical phenomena which present themselves when substances change their state, and would leave that change itself unaccounted for. It cannot, therefore, be admitted. Various other methods of ascertaining the absolute heat of bodies have been proposed; but, as they are all unsatisfactory, it is not necessary to detail them here.

SECT. VI. *Of the Sources of Caloric.*

Of the sources of caloric.

The most important sources of heat are the five following, the *sun*, *combustion*, *percussion*, *friction*, and *mixture*.

1. *The Sun.*

The sun.

The sun is an immense globe, the diameter of which is 888,246 miles. It was long supposed to be in a state of violent combustion. But the curious observations of Dr Herschel render it probable that this notion is erroneous. From them it appears, that the sun is an opaque globe, surrounded by an atmosphere of great density and extent. In this atmosphere, there float two regions of clouds. The lowermost of the two is opake, and similar to the clouds which form in our own atmosphere; but the higher region of clouds is luminous, and emits the immense quantity of light to which the splendour of the sun is owing.

Solar rays.

The sun emits three kinds of rays; the *calorific*, *colorific*, and *deoxidizing*. The first occasions *heat*, the second *colour*, and the third separates *oxygen* from various bodies.

When the solar rays strike transparent bodies, they produce very little effect; but opake bodies are heated by them. They pass through transparent bodies; but are retained, at least in part, by opake bodies. The deeper the colour of the opake body, the greater is the heat produced. Black bodies are most heated, and white least, and the others in proportion to the intensity of the colour. The temperature produced in bodies by the direct action of the sun's rays, seldom exceeds 120°. But when the heat is prevented from escaping, as, by enclosing a thermometer within a glass vessel whose bottom is cork, the temperature sometimes rises nearly to 240°. When the sun's rays are accumulated by means of burning glasses, the most intense heat is produced that it is possible to raise by any known method.

2. *Combustion.*

Combustion.

Few phenomena are more wonderful or interesting than *combustion*. When a stone or a brick is heated it undergoes no change, and, when left to itself, it soon cools again, and becomes as at first. But, when combustible bodies are heated to a certain degree in the open air, they suddenly become much hotter of themselves, continue for a certain time intensely hot, and send out a copious stream of light and heat. When this ceases, the combustible has undergone a most complete change, being converted into a substance possessed of very different properties, and no longer capable of combustion.

The first ingenious attempt to explain combustion was by Dr Hooke. According to him, there is an ingredient in air capable of dissolving combustibles when their temperature is sufficiently raised. The solution takes place with such rapidity, that it occasions light and heat, which, in his opinion, were mere motions. The quantity of this solvent in air is not great. Hence the reason why so great a proportion of air is necessary to support combustion. This hypothesis was embraced by Mayow, but without making any great addition either to its evidence or probability.

Hypothesis of Stahl.

Beccher and Stahl soon after advanced another, which was much more universally embraced. According to them, all combustible substances contain in them a certain body called *phlogiston*, to which they owe their combustibility. This substance is the same in all combustible bodies. They owe their diversity to other ingredients combined with the phlogiston. During the combustion, the phlogiston separates, and the incombustible ingredients remain behind. The light and the heat are occasioned by the violent motion into which the phlogiston is thrown during its emission.

Light being considered as a body, occasioned a change in the Stahlian theory. Phlogiston was considered as nothing else than light fixed in bodies. When heat, in consequence chiefly of the discoveries of Dr Black, came to be considered as a body, the opinion respecting phlogiston got a new modification. It was considered as a subtile fluid, the same with the *ether* of Hooke and Newton, which occasioned gravity, and gave the bodies, called *heat* and *light*, the peculiar motions which produce in us the sensations of heat and light.

Of Priestley.

Dr Priestley first attempted to account for the necessity of air for combustion. Air, according to him, has an affinity for phlogiston; it draws it out of the combustible body, and combines with it. But if so, whence come the heat and the light, which make their appearance in all cases of combustion? According to Dr Crawford, they existed in the air, and were displaced by the phlogiston when it united with that fluid.

These modifications of the Stahlian theory were evidently improvements. But they left the nature of phlogiston altogether out of view. Kirwan first attempted to ascertain what this substance was, and to prove it the same with what is now called *hydrogen gas*. This opinion he supported in an ingenious Essay on *Phlogiston*; and it was embraced by many of the most respectable chemists in Europe.

Of Lavoisier.

Meanwhile, Mr Lavoisier had been investigating the subject with the minutest attention, and, after a very long, elaborate, and ingenious examination, had satisfied himself, that, in every case of combustion, oxygen unites with the burning body. For a long time nobody would accede to his opinion; but at last, in 1785, Berthollet and Fourcroy joined him, and soon after Guyton-Morveau came over to his sentiments. They wrote a refutation of Mr Kirwan's essay, which was so satisfactory, that Mr Kirwan himself came over to their opinion. And after a short, but pretty violent controversy, the Lavoisierian theory of combustion was universally adopted. According to this theory, combustion consists of two processes, a *combination* and a *decomposition*. The oxygen of the air *combines* with the combustible, and gives out the *heat* and *light* with which it was previously *united*.

The following observations may, perhaps, contribute somewhat to elucidate what is still obscure in this curious process.

All bodies, as far as combustion is concerned, may be divided into *supporters*, *combustibles*, and *incombustibles*. By supporters, are meant certain bodies, not indeed capable of burning, but combustion cannot go on without their presence. *Air*, for example, is a supporter. *Combustibles* and *incombustibles* require no explanation.

List of supporters.

Oxygen and chlorine are the only simple supporters known. When they combine with an incombustible, they form a compound supporter. The following are all the supporters at present known:

1. Oxygen.
2. Chlorine.
3. Air.
4. Nitrous oxide.
5. Nitrous gas.
6. Nitric acid.
7. Euchloric gas.

The combustibles are either the simple substances which have been already described, or combinations of these with each other, or with oxygen without combustion; in which last case, they may be called combustible oxides.

Products.

During combustion, the oxygen or chlorine of the supporter always combines with the combustible, and forms with it a new substance, which may be called a *product* of combustion. Now every product is either, 1. Water; 2. An acid; or, 3. A metallic oxide.

Partial supporters.

Some products are capable of combining with an additional dose of oxygen. But this combination is never attended with combustion, and the product, in consequence, is converted into a supporter. Such compounds may be called *partial supporters*, as a part only of the oxygen which they contain is capable of supporting combustion.

Since oxygen is capable of supporting combustion only in the supporters and partial supporters, it is clear that it is in a different state in these bodies from what it is in products. It is probable that, in supporters, it contains combined with it a considerable quantity of heat, which is wanting in products.

Combustion explained.

It is probable, that combustible bodies contain light as a constituent. For the quantity of light emitted during combustion depends upon the combustible; while the heat seems, in some measure at least, to depend upon the oxygen. If these two suppositions be admitted, the phenomena of combustion admit of an easy explanation. The base of the oxygen and of the combustible combine together, and form the product; while the heat of the one and the light of the other in like manner unite, and fly off in the form of fire.

3. *Percussion.*

Percussion.

It is well known, that heat is produced by the percussion of hard bodies against each other. Iron may be heated red hot by striking it with a hammer, and the sparks emitted by flint and steel are well known.

Percussion occasions condensation.

This evolution of heat appears to be the consequence of the permanent or temporary condensation of the bodies struck. Iron and most metals become specifically heavier when hammered. Now condensation always evolves heat. When air is condensed, it gives out a considerable quantity of heat, sufficient to set fire to tinder. When muriatic acid gas is passed through water, it is condensed, and the water becomes hot. On the other hand, when air is rarefied, it becomes suddenly much colder.

It is not difficult to see why condensation evolves heat. The particles being forced nearer each other, the repulsive force of the heat is increased, and a portion in consequence is driven off. The specific caloric of bodies is diminished by condensation. Now the specific caloric can scarcely be conceived to diminish without the body giving out heat.

A part of the heat which follows percussion, is often owing to another cause. By the percussion, the heat of the body is raised so high, that combustion commences, and this occasions a still farther increase of the heat. It is in this way that sparks are produced when flint and steel are struck. The sparks are small pieces of the steel which have taken fire and melted during their passage through the air.

4. *Friction.*

Friction.

Heat is not only evolved by percussion, but also by friction. And not only by the friction of hard bodies, but even of soft bodies, as when the hand is rubbed against the sleeve of the coat. No heat has ever been observed from the friction of liquids.

The heat evolved by friction seems to be owing to the same cause as that by percussion; namely, a condensation of the substances rubbed. This condensation is, in some cases, permanent; but when the bodies rubbed are soft, it can only be momentary.

The heat evolved by friction is sometimes very considerable. Thus Count Rumford boiled water by the heat evolved by rubbing a steel borer against a cylinder of gun-metal. Probably in this case the density of the metal was a little increased. A very small increase would account for the whole heat evolved.

5. *Mixture.*

Mixture.

In a great number of cases, a change of temperature takes place when bodies combine chemically with each other. Sometimes the compound becomes colder than before, and sometimes hotter.

Change of temperature by mixture owing to water.

When Glauber's salt in crystals pounded is dissolved in water, a considerable degree of cold is produced; and the cold is still more intense, if the salt be dissolved in muriatic acid. If muriate of lime, in powder, and dry snow be mixed together, so great a degree of cold is produced, that mercury may be frozen if it be surrounded by such a mixture. Potash and snow produce an equally great cold. When nitric acid or sulphuric acid is poured upon snow, the snow dissolves, and an intense cold is produced.

On the other hand, when sulphuric acid and water are mixed, so great a heat is evolved, that the liquid is considerably hotter than boiling water. Heat also is produced, when nitric acid and water, or water and alcohol, are mixed together. Heat also is produced if Glauber salt, in a state of efflorescence, is dissolved in water. An intense heat is produced by dissolving quick-lime in sulphuric acid.

In most of these cases of change of temperature, water is either one of the substances combined, or it forms an essential constituent of one of them. The heat or the cold produced, depends often on this constituent. Thus Glauber's salt, containing its water of crystallization, produces cold when dissolved; while the same salt, deprived of its water of crystallization, produces heat.

If the new compound be more fluid than the two constituents of it, the temperature sinks; if it be less fluid, the temperature rises. Thus, when snow and common salt are mixed, they gradually melt and assume the form of a liquid, and the temperature sinks to zero. Solid water cannot become liquid, without combining with a quantity of heat; and the same rule applies to all solid bodies which become liquid. Hence the cold evolved in these cases. The water of crystallization in Glauber's salt is solid: it becomes liquid when the salt is dissolved. Hence the cold produced. When the same salt, free from its water of crystallization, is thrown into water, it first combines with a portion of the water, and renders it solid. Hence the heat evolved. Dr Black's doctrine of latent heat affords a satisfactory explanation of these phenomena.

Or to the specific heat changing.

When the density of two liquids united is greater than the mean, heat is evolved, because the specific caloric of the new compound is less than that of the constituents. This was first observed by Dr Irvine, and it accounts for the heat evolved when water is mixed with sulphuric acid, nitric acid, or alcohol.

Thus it appears, that the changes of temperature produced by mixture, are either occasioned by the change of state which the water undergoes, or by a diminution of specific caloric, in consequence of the new combination.

BOOK II.

OF COMPOUND BODIES.

Of compound bodies.

Compound bodies are substances composed of two or more simple substances united together. They amount to several thousands; but the present state of the science does not permit us to give an account of them all under their proper heads.

Two classes of compounds.

Compound bodies are of two kinds. Some are formed by the combination of two or more simple substances with each other; while others are formed by the union of two or more compound bodies with each other. To the first class belong *phosphoric acid*, composed of phosphorus and oxygen; and *ammonia*, composed of azote and hydrogen. To the second class belongs *phosphate of ammonia*, composed of phosphoric acid and ammonia. The first of these sets we shall call *primary compounds*; to the second we shall give the name of *secondary compounds*.

DIVISION I.

Of Primary Compounds.

Of primary compounds.

The primary compounds, such of them at least as we are sufficiently well acquainted with to introduce here, may be arranged under the following heads:

1. Alkalies.
2. Earths.
3. Oxides.
4. Acids.
5. Compounds of chlorine.
6. Compound combustibles.

These shall be the subject of the six following Chapters.

Chap. I.

Of Alkalies.

The term *alkali* was introduced into chemistry, after having been applied to a plant that still retains the name of *kali.* When this plant is burnt, the ashes washed in water, and the water evaporated to dryness, a white substance remains, called *alkali.* Alkali may be obtained from many other bodies besides this plant. Chemists gradually discovered that different substances had been confounded together under the name of alkali. The word, in consequence, became general, and is now applied to all substances having the following properties.

Alkali explained.

1. A caustic taste.
2. Volatilized by heat.
3. Capable of combining with acids, and of destroying their acidity.
4. Soluble in water, even when combined with carbonic acid.
5. Capable of converting vegetable blues to green.

The alkalies at present known are three in number; 1. Ammonia; 2. Potash; 3. Soda. The first is called *volatile alkali;* the two last *fixed alkalies.*

Sect. I. *Of Ammonia.*

Ammonia, how obtained.

Put into a retort a mixture of three parts quicklime, and one part sal-ammoniac; plunge the beak of the retort into a trough filled with mercury. Apply heat. A gas comes over, which may be received in glass jars filled with mercury. This gas is *ammonia.*

Its properties.

This gas possesses the mechanical properties of common air. Its taste is acrid and pungent, and it has a strong smell, not unpleasant when diluted. Animals cannot breathe it, and combustibles do not burn in it. Its specific gravity is 0.600, that of air being 1.000. At the temperature of 60°, 100 cubic inches of it weigh 18.16 grains. When exposed to a cold of —45°, it is condensed into a liquid. When passed through a red-hot tube, it is decomposed and converted into hydrogen and azotic gases.

Water absorbs it with great rapidity. This liquid absorbs 780 times its bulk of this gas; and six parts of water, by this absorption, increase in bulk to 10 parts. The specific gravity of this solution is 0.900. It is in this state that ammonia is commonly used. It was known to the alchymists, and called *hartshorn, spirit of urine,* and *spirit of sal ammoniac.*

Composition.

Ammoniacal gas is not altered by light, but when electric sparks are made to pass through it, its bulk is nearly doubled, and it is converted into hydrogen and azotic gases. Hence it follows, that it is composed of hydrogen and azote. The most exact experiments make the proportion of the constituents, three parts, in bulk, of hydrogen gas, and one part of azote; or in weight,

81.5 azote,
18.5 hydrogen.
———
100.0

Action of oxygen.

When mixed with oxygen gas, it detonates by electricity, and is decomposed, as Dr Henry has ascertained. To analyse ammonia by means of oxygen, it ought to be first mixed with half its bulk of oxygen gas. An electric spark occasions a combustion; but the whole of the hydrogen is not consumed. By adding another quantity of oxygen gas, a new combustion may be produced. Double the oxygen gas consumed indicates the bulk of hydrogen, and the azote remaining in the residuary gas, its bulk may be estimated.

Chlorine.

When mixed with chlorine, it burns with considerable splendour; and a quantity of sal-ammoniac is formed at the same time.

Sulphur.

Sulphur is the only one of the simple combustibles that combines with ammonia. The combination may be produced by mixing it with sulphur in the state of vapour, or better by distilling a mixture of equal weights of sal-ammoniac, sulphur, and quick-lime diluted with a little water. A yellow liquid comes over, which consists of water, holding in solution ammonia and sulphur. It contains an excess of ammonia.

When ammonia comes in contact with phosphorus at a red heat, it is decomposed, and phosphureted hydrogen gas formed. When ammoniacal gas is made to pass through red-hot charcoal, a substance is formed called *prussic acid.*

Ammonia is not acted on by azote.

Action of metals.

Ammonia is capable of oxidizing some of the metals, and of dissolving the oxides formed. Liquid ammonia dissolves the oxides of silver, copper, iron, tin, nickel, zinc, bismuth, and cobalt. When digested upon the oxides of mercury, lead, or manganese, it is decomposed, water formed, and azotic gas emitted. It combines readily with the peroxides of gold and silver; and forms two remarkable compounds, known by the names of *fulminating gold* and *silver.*

Fulminating gold.

Fulminating gold may be obtained by dissolving gold in aqua regia, and precipitating it by ammonia. A yellow precipitate falls, which is to be washed and dried. It is fulminating gold. It is composed of five parts yellow oxide of gold, and one part of ammonia. It fulminates violently, when heated to the temperature of about 300° or 400°; also when struck violently with a hammer, or when triturated in a mortar. Water is formed, and azotic gas emitted.

Fulminating silver.

Fulminating silver was discovered by Berthollet. It may be prepared by dissolving silver in nitric acid, precipitating by lime-water, drying the precipitate in a filter, and then keeping it for twelve hours in liquid ammonia. Its tendency to explode is so strong, that it is dangerous to prepare it except in small quantities.

Ammonium.

If a globule of mercury be put into a hollow in a moistened piece of sal ammoniac, and exposed to the energy of a powerful galvanic battery, it increases in bulk, and acquires the consistency of butter. Its specific gravity is reduced to 3. The mercury has obviously amalgamated with some metallic body. If this amalgam be thrown into water, the mercury resumes its original state, a little hydrogen gas is exhaled, and the water is impregnated with a weak solution of ammonia. Hence it would appear, that the amalgamating metal is the basis of ammonia; that it decomposes water, emits the hydrogen, and retains the oxygen; and that, by this combination, it is converted into ammonia. This unknown metallic basis of ammonia has been called *ammonium*.

Sect. II. *Of Potash.*

Potash, how procured.

Potash, called also *vegetable alkali*, is obtained from the ashes of trees, and of vegetables that grow at a distance from the sea-shore. These ashes are lixiviated with water; the water evaporated to dryness; the residual salt mixed with twice its weight of quicklime, and a sufficient quantity of water to make the whole into a thin paste. The water is drawn off in 24 hours, boiled to dryness in a clean iron pot, and then mixed with a quantity of alcohol, equal in weight to half the original salt. The alcoholic solution, after standing some days in well-closed phials, is decanted off, and the alcohol distilled away in a silver still. The substance which remains behind is pure potash.

Its properties

Potash is a brittle substance, of a white colour, and a smell like that which is perceived during the slacking of quick-lime. Its taste is extremely acrid, and it is very corrosive, destroying the texture of most animal and vegetable bodies to which it is applied. Its specific gravity is 1.7085.

When heated, it melts. At a red heat, it evaporates in a white acrid smoke.

It contains about one-fourth of its weight of water, even after being exposed to a red heat. When exposed to the air, it speedily absorbs moisture, and runs into a liquid. At the same time, it combines with carbonic acid, for which it has a strong affinity.

Water dissolves twice its weight of potash. The solution is limpid and colourless, and almost of the consistency of an oil. It is in this state that potash is commonly used by chemists. When evaporated to the proper consistency, the potash crystallizes.

Combination with sulphur.

2. Potash does not combine with any of the simple combustibles, except sulphur. The combination takes place by simple trituration of the two substances in a mortar, or by fusing them in a crucible. This compound is called *sulphuret of potash*. It was formerly distinguished by the name of *hepar sulphuris*, or *liver of sulphur*. Its colour is brown; it is hard, brittle, and has a glassy fracture. Its taste is acrid and bitter, and it leaves a brown stain on the skin. It converts vegetable blues to green, and soon destroys them. When exposed to the air, it acquires a green colour, and emits the smell of sulphureted hydrogen. In this state it is a triple compound, being composed of sulphur, potash, and sulphureted hydrogen. The last ingredient is formed by the decomposition of the water absorbed from the atmosphere. It dissolves in water, and forms a greenish yellow solution. In this state it is called *hydrogureted sulphuret of potash*.

When liquid potash and phosphorus are heated in a retort, water is decomposed, and *phosphureted hydrogen* gas is formed and comes over. This gas possesses the curious property of taking fire when it comes in contact with the air.

3. Potash does not unite with azote.

4. Several of the metals, when kept in liquid potash, are oxidized, water being decomposed. This is the case with iron, zinc, and molybdenum; and probably also with tin and manganese.

Potash dissolves the oxides of lead, tin, nickel, arsenic, cobalt, manganese, zinc, antimony, tellurium, tungsten, molybdenum.

Potassium.

Mr Davy has lately succeeded in decomposing potash, and in showing that it is a compound of oxygen and a peculiar metal, to which he has given the name of *potassium*. The decomposition was accomplished by exposing potash to the action of the galvanic battery. The metallic base separated at the negative extremity, while oxygen was evolved at the other. More lately, Thenard and Gay-Lussac have ascertained, that potash is decomposed, and potassium obtained, when it is made to come in contact with iron turnings heated to whiteness in a gun-barrel.

Its properties.

Potassium, the base of potash, possesses the following properties. It is white like mercury. At 50°, it is a soft malleable solid, which becomes imperfectly liquid at 60°, and perfectly so at 100°. While at 32°, it is hard, brittle, and crystallized in facets. It is not only lighter than water, but lighter than any known liquid. Its specific gravity does not exceed 0.885. Its affinity for oxygen is very great. In the open air, it is covered with a crust of potash in a few minutes. When thrown upon water, it decomposes that liquid with rapidity; hydrogen gas, holding potassium in solution, is disengaged and takes fire, which occasions the combustion of the whole potassium.

When heated in a small quantity of oxygen gas, it loses its metallic appearance, and assumes a reddish brown colour. In this state it may be considered as a peroxide of potassium.

Chlorine sets potassium on fire, and converts it into muriate of potash.

It combines with phosphorus, and forms a phosphuret, which has the colour of lead, and remains solid at a heat little short of that of boiling water. In the open air it burns, and is converted into phosphate of potash.

It combines rapidly with sulphur by heat, and heat and light are emitted at the moment of combination. The sulphuret has a grey colour, and in the open air, is soon converted into sulphate of potash.

It combines and forms alloys with all the metals tried, but these alloys are soon destroyed in the open air, or in water, and the potassium converted into potash.

Constituents of potash.

Potash, according to the experiments of Mr Davy, is composed of about

86 potassium,
14 oxygen.
———
100

According to Thenard and Gay-Lussac, it is composed of

83.371 potassium,
16.629 oxygen.
———
100

SECT. III. *Of Soda.*

Soda, how procured.

Soda, called also *fossil* or *mineral alkali*, is found in large quantities ready formed in the earth. It may be obtained also from the ashes of the different species of *salsola* and other marine plants. The process is the same as that for procuring potash.

Its properties.

When pure, it has a very strong resemblance to potash in most of its properties.

Its colour is greyish white, and it agrees with potash in its taste, smell, and action on animal bodies. Its specific gravity is 1.336.

Heat produces the same effects on it as on potash. In the open air, it absorbs water and carbonic acid, but it does not become liquid as potash does. After assuming the state of a paste, it soon dries again, and crumbles to powder.

It dissolves in water like potash, and may be obtained crystallized. The action of oxygen, of the simple combustibles and incombustibles, is similar to their action on potash. The same remark applies to the metals and their oxides.

Sodium.

Like potash, it is a compound of oxygen and a peculiar metal, to which Mr Davy, the discoverer, has given the name of *sodium*. It may be decomposed precisely in the same way as potash.

Its properties.

Sodium is a white metal like silver, solid, but very malleable, and so soft, that pieces may be welded together by strong pressure. At 120°, it begins to melt; and is completely fluid at 180°. It is not volatilized in a red heat strong enough to melt plate-glass. It conducts electricity and heat in the same manner as potassium. Its specific gravity is 0.9348.

Its affinity for oxygen is similar to that of potassium. When exposed to the air, it is soon covered with a crust of soda; but as that alkali does not deliquesce, the nucleus is not so soon destroyed as happens to potassium. Hydrogen gas does not dissolve it. Hence no combustion takes place when sodium is thrown upon water, though it rapidly decomposes that liquid.

When fused with dry soda in certain quantities, there is a division of oxygen between the soda and the base, and a protoxide of sodium is formed, of a deep brown colour. It is capable likewise of absorbing an additional dose of oxygen, and of forming a peroxide.

Composition of soda.

It burns like potassium in chlorine. It combines with phosphorus, sulphur, and the metals, like potassium. From the experiments of Mr Davy, it appears that soda is composed of

Sodium 78
Oxygen 22
———
100

According to Thenard and Gay-Lussac, it is composed of

Sodium 74.63
Oxygen 25.37
———
100

Thus it appears, that the two fixed alkalies are metallic deutoxides. It is very probable that ammonia is likewise an oxide, though the metallic base of which it consists has not yet been obtained in a separate state.

CHAP. II.

Of the Alkaline Earths.

Earth explained.

The term *earth*, in chemistry, is applied to all substances possessing the following properties.

1. Insoluble in water, or at least becoming insoluble when combined with carbonic acid.
2. Little or no taste or smell, at least when combined with carbonic acid.
3. Fixed, incombustible, and incapable, when pure, of being altered by the fire.
4. A specific gravity not exceeding 4.9.
5. When pure, capable of assuming the form of a white powder.
6. Not altered when heated with combustibles.

The earths have been divided into two classes, namely, *alkaline earths*, and *earths proper*. The alkaline are four in number, namely, *lime*, *magnesia*, *barytes*, and *strontian*.

SECT. I. *Of Lime.*

Lime.

Lime has been known from the remotest ages. It abounds in every part of the earth, constituting immense ranges of rocks and mountains. It may be obtained by *burning* those crystallized limestones called *calcareous spars*, or certain white marbles. Oyster shells, also, when burnt, yield it nearly pure.

Its properties.

Pure lime is white, moderately hard, but easily reduced to powder. Its taste is acrid like that of the fixed alkalies, and it in some measure corrodes those animal bodies to which it is applied. Its specific gravity is 2.3. It tinges vegetable blues green, and at last renders them yellow. It does not melt in the most violent heat that can be applied.

Hydrate of lime.

When water is poured upon it, the lime swells and falls to pieces, and so much heat is evolved as to evaporate a portion of the water, and even to set fire to combustible substances with which it happens to be in contact. This process is called *slacking* the lime. A portion of the water combines with the lime, and becomes solid. Hence the cause of the heat evolved. Slacked lime is composed of 3 parts lime and 1 water. It has been called *hydrate of lime*.

The difference between *limestone* and *lime* was first ascertained by Dr Black. Limestone is lime combined with carbonic acid. By burning it, the carbonic acid is driven off, and the pure lime remains.

When lime is exposed to the open air, it gradually attracts moisture, falls to powder, and, becoming saturated with carbonic acid, soon resumes its original state of limestone.

Lime-water.

Water dissolves less than 0.002 parts of its weight of lime. The solution is called lime-water. It is limpid, has an acrid taste, and changes vegetable blues to green. When exposed to the air, the lime soon combines with carbonic acid and precipitates, leaving the water pure. From the experiments of Mr Dalton, it appears that cold water dissolves twice as much lime as hot water.

Lime has the property of absorbing oxygen. Sulphur and phosphorus are the only two simple combustibles that unite with it.

Sulphuret.

Sulphuret of lime may be formed by mixing its two constituents together, and heating them in a crucible. The mass has a reddish colour. In the air it becomes greenish yellow, sulphureted hydrogen is formed, and the mass is converted into *hydrogureted sulphuret of lime*. This last compound may be formed by boiling a mixture of sulphur and lime in about ten times its weight of water. The solution has a yellow colour, and is used for absorbing oxygen from air.

Phosphuret.

Phosphuret of lime may be formed by passing phosphorus through red-hot lime in a glass tube. It has a deep brown colour, and falls to powder in the air. When thrown into water, bubbles of phosphureted hydrogen gas are emitted, which take fire as they separate from the liquid.

Lime does not unite with azote.

Lime facilitates the oxidizement of several of the metals. It dissolves some metallic oxides, as those of mercury and lead.

It does not unite with the alkalies.

Calcium.

Mr Davy has lately ascertained that lime, like the fixed alkalies, is a compound of oxygen and a peculiar metal, to which he has given the name of *calcium*. He decomposed lime, by exposing a mixture of moistened lime and red oxide of mercury to the action of a galvanic battery. A globule of mercury was placed in the middle of the mixture. The lime was decomposed, and its base united with the mercury, and formed an amalgam. The mercury was distilled off in glass tubes filled with the vapour of naphtha, and the *calcium* remained behind.

Calcium is white like silver, solid, and four or five times heavier than water. When heated, it burns brilliantly, and quick-lime is produced.

SECT. II. *Of Magnesia.*

Magnesia,

Magnesia was discovered about the beginning of the 18th century, by a Roman canon. But little was known about its nature, till Dr Black made his celebrated experiments on it in 1755.

how obtained.

It may be procured from the salt called *sulphate of magnesia*, or *Epsom salt*, by dissolving the salt in water, and pouring potash into the solution. A white matter falls; when washed and dried it is pure magnesia.

Its properties.

Magnesia is a very soft light powder, with very little taste, and destitute of smell. Its specific gravity is 2.3. It tinges vegetable blues green. It does not melt in the strongest heat that can be raised.

It is not sensibly soluble in water, and has never been exhibited in a crystallized form. When exposed to the air, it attracts carbonic acid very slowly.

It does not combine with oxygen, nor with any of the simple combustibles except sulphur. The sulphuret of magnesia may be formed, by mixing the two constituents, and exposing it to a moderate heat. The result is a yellow powder slightly agglutinated.

It does not combine with azote.

It has no action on the metals, nor is it known to combine with any of their oxides. Neither does it unite with the fixed alkalies or with lime.

Magnium.

Mr Davy succeeded in decomposing magnesia, by the same process that furnished him with the base of lime. Like lime it is composed of oxygen and a metal, to which the name of *magnium* has been given. This metal is white, sinks rapidly in water, absorbs oxygen when exposed to the air, and is converted into magnesia. It decomposes water, but not nearly so rapidly as the other alkaline metals, owing doubtless to the insolubility of magnesia.

SECT. III. *Of Barytes.*

Barytes, how obtained.

Barytes was discovered by Scheele in 1774. It is usually obtained from a heavy foliated brittle mineral, pretty common, and called *ponderous spar*, or *sulphate of barytes*. This mineral is mixed with charcoal powder, and exposed to a strong heat in a crucible. It is then dissolved in water, and saturated with nitric acid. The liquid, filtered and evaporated, yields crystals, which being exposed to a strong heat in a crucible, leave behind them an earthy matter, which is barytes.

Its properties.

Barytes thus obtained is a greyish white porous body, and may be easily reduced to powder. Its taste is more caustic than that of lime, and when swallowed it acts as a violent poison. Its specific gravity is 2.374. When water is poured on it heat is evolved, and the barytes is *slacked* precisely as happens to lime. By this means it combines with water, and is converted into *hydrate of barytes*.

Water dissolves about 0.05 of its weight of barytes. The solution has an acrid taste, and tinges vegetable blues green. Boiling water dissolves more than half its weight of barytes. As the solution cools, the barytes precipitates in crystals.

Barytes absorbs oxygen, but does not combine with any of the simple combustibles except sulphur and phosphorus. The sulphuret and phosphuret of barytes may be formed precisely in the same way as those of lime, which they resemble in most of their properties.

Barytes is not acted on by azote.

Barytes has no action on the metals, but it combines with some of the metallic oxides, and forms compounds hitherto scarcely examined.

It does not combine with the alkalies, nor has it much action upon lime or magnesia.

Barium.

Mr Davy has shown, that barytes, like the preceding earths, is a metallic oxide, being composed of oxygen and a metal, to which the name of *barium* has been given. The *barium* was obtained by the same process as that which furnished him the bases of lime and magnesia. It is a white solid metal, melts at a heat below redness, and is not volatilized at the temperature capable of melting plate-glass. It is at least four or five times heavier than water. It decomposes that liquid with great rapidity, and is converted into barytes. It undergoes the same change when exposed to the open air.

SECT. IV. *Of Strontian.*

Strontian,

Strontian was first discovered in the lead mine at Strontian in Argyleshire. It was suspected to be a peculiar earth by Dr Crawford in 1790, and its properties were soon after investigated by Dr Hope. Klaproth and Kirwan also ascertained its peculiarity. It is found sometimes combined with carbonic acid, sometimes with sulphuric acid. From the first compound, it may be obtained by making the mineral into a ball with charcoal powder, and exposing it to a violent heat; and from the second, by treating it precisely in the way described in the last Section for obtaining barytes.

how obtained.

Its properties.

Strontian thus obtained, is a porous mass of a greyish white colour. Its taste is acrid and alkaline, and it changes vegetable blues to green. Its specific gravity is 1.647. It is not poisonous.

When water is thrown upon it, the strontian becomes hot, combines with water, and is *slacked* like quick-lime. It is soluble in water, 162 parts of that liquid taking up one part of strontian. Hot water dissolves a much larger quantity, and the strontian crystallizes as the solution cools.

Strontian does not combine with oxygen. The only simple combustibles that unite with it are sulphur and phosphorus. The sulphuret and phosphuret of strontian may be formed precisely as the same compounds of lime, and possess nearly similar properties.

Strontian does not combine with azote.

It has no action on the metals, but it combines with some of the metallic oxides. It does not unite with the alkalies, nor with the other alkaline earths.

It tinges flame of a beautiful red colour. The experiment may be made by setting fire to paper dipt in an alcoholic solution of muriate of strontian.

Strontium.

Mr Davy has ascertained, that strontian, like the other alkaline earths, is composed of oxygen and a peculiar metal, to which he has given the name of *strontium*. This metal bears a close resemblance to *barium* in its properties.

CHAP. III.

Of the Earths Proper.

Of the earths proper.

THE earths proper neither neutralize acids, nor produce any change on vegetable blues. They are five in number; namely, *alumina, yttria, glucina, sirconia, silica.*

SECT. I. *Of Alumina.*

Alumina, how obtained.

Alumina may be obtained from the salt called *alum*, by the following process. Dissolve alum in water; pour ammonia into the solution, a precipitate appears; separate this precipitate and wash it; then boil it in liquid potash till the whole is dissolved; pour a solution of sal ammoniac into this liquid, a white matter precipitates, which, when washed and dried, is pure alumina.

Its properties.

Alumina is a white matter in powder. It has no taste, and when pure no smell. Its specific gravity is 2.000.

When heat is applied to alumina, it gradually loses weight, in consequence of the evaporation of moisture; at the same time its bulk is diminished. Alumina undergoes a diminution of bulk proportional to the heat to which it is exposed. Mr Wedgewood took advantage of this property, to contrive an instrument for measuring high temperatures. It consists of pieces of clay of a determinate size, and an apparatus for measuring their bulk with accuracy. One of these pieces is exposed to the heat, and the temperature is judged of by the contraction. This contraction is measured by means of two brass rules fixed to a plate. The distance between them at one extremity is 0.5 inch, and at the other extremity 0.3 inch. These rules are 24 inches long, and divided into 240 equal parts, called degrees. These degrees commence at the wide end of the scale. The first corresponds with 947° of Fahrenheit, or a red heat.

Wedgewood's pyrometer.

Alumina is not soluble in water, though it has a strong affinity for that liquid. It may be knedded with it into a very ductile paste, possessed of a good deal of tenacity. Clay owes its ductility to the alumina which it contains. It retains water with more obstinacy than any of the other earths.

Alumina has no effect upon vegetable blues. It cannot be crystallized artificially, but it is found native in beautiful crystals, constituting the precious stone called sapphyr.

It neither combines with oxygen, nor with any of the simple combustibles. Azote has no action on it.

It does not unite with the metals, but it has an affinity for several metallic peroxides.

The fixed alkalies dissolve it readily when they are in a state of solution in water; but they do not melt with it when heated in a crucible. Barytes and strontian combine with alumina, both when heated with it in a crucible, and when boiled with it in water. It has a strong affinity for lime, and easily melts with it when it exceeds the lime in quantity; but when the lime exceeds, fusion does not take place. Magnesia and alumina have no action on each other.

Alumium.

It is probable that alumina, like the alkaline salts, is a metallic oxide. This notion was entertained long ago by chemists. Davy endeavoured to obtain the metallic basis by means of galvanism, but did not succeed, though he has rendered it probable that a metal exists in it. To this metal he proposes to give the name of *alumium*.

SECT. II. *Of Yttria.*

Yttria, how obtained.

This earth was discovered by Gadoline in a Swedish mineral of a black colour, to which the name Gadolinite has been given. To obtain it, the mineral is reduced to powder, dissolved in nitro-muriatic acid, filtered, evaporated to dryness, redissolved, filtered, evaporated to dryness, the residual salt is heated to redness, redissolved in water, and ammonia poured into the solution. A white powder falls, which is yttria.

Yttria, thus procured, is a fine white powder without taste or smell. It has no action on vegetable blues. Heat does not melt it. Its specific gravity is 4.842.

Its properties.

It is insoluble in water, but, like alumina, it retains a portion of that liquid, though not with so much obstinacy.

It is insoluble in the liquid fixed alkalies; but it dissolves in carbonate of ammonia, and in all the other alkaline carbonates.

It does not combine with oxygen, the simple combustibles, or azote.

According to Ekeberg, when yttria is treated with muriatic acid, a quantity of chloric gas is formed. If so, it must contain oxygen, and of course be a metallic oxide. The opinion is probable, though no attempts have been made to decompose yttria by means of galvanism.

Sect. III. *Of Glucina.*

Glucina, how obtained.

Glucina was discovered by Vauquelin in the two minerals called beryl and emerald. They are pounded and fused with thrice their weight of potash. The mass is dissolved in muriatic acid, and the solution evaporated to dryness. The residuum is digested in water, and thrown upon the filter. The liquid which passes through is mixed with carbonate of potash, and the precipitate dissolved in sulphuric acid. Sulphate of potash being added to the solution, it is laid aside for some time. Alum crystals gradually form. When no more appear, filter the liquid, add carbonate of ammonia in excess, filter again and boil the liquid for some time. A white powder precipitates, which is glucina.

Its properties.

Glucina is a soft white powder, without either taste or smell. It adheres strongly to the tongue, produces no change on vegetable blues, does not melt when heated, and does not harden and contract like alumina. Its specific gravity is 2.976. It is insoluble in water, but forms with it a paste having some ductility.

It does not combine with oxygen, nor with the simple combustibles, or azote.

It is soluble in the liquid fixed alkalies, like alumina; is insoluble in ammonia, but, like yttria, soluble in carbonate of ammonia.

Mr Davy has rendered it probable, that it is a metallic peroxide. To the metallic basis he proposes to give the name of *glucium.*

Sect. IV. *Of Zirconia.*

Zirconia, how obtained.

Zirconia was discovered by Klaproth in the two minerals called *jargon* or *zircon*, and the hyacinth. Fuse the pounded mineral with thrice its weight of potash; wash the mass in pure water till the whole of the potash is extracted, then dissolve the residuum as far as possible in muriatic acid; boil the solution, filter and add a quantity of potash. The zirconia precipitates in the state of a fine powder.

Its properties.

Zirconia is a white powder with a harsh feel. It has neither taste nor odour, is infusible before the blowpipe, but when violently heated, acquires the appearance of porcelain. In this state it is hard, and its specific gravity is 4.3. It is insoluble in water, but, when precipitated from a solution and dried slowly, it retains water, and assumes the appearance of gum arabic.

It does not combine with oxygen, simple combustibles, azote, nor metals. But it has an affinity for several metallic oxides.

It is insoluble in liquid alkalies, and infusible with them; but it is soluble in alkaline carbonates.

Mr Davy has made it probable, that it is a metallic peroxide. To the metallic basis he proposes to give the name of *zirconium.*

Sect. V. *Of Silica.*

Silica, how obtained.

The minerals called *quartz*, *rock-crystal*, *flint*, &c. consist almost entirely of this earth. It may be obtained in the following manner. Melt in a crucible a mixture of one part quartz powder, and three parts potash; dissolve the mass in muriatic acid, and evaporate to dryness; towards the end of the evaporation, the liquid assumes the form of a jelly; wash the residue in water, and dry it.

Its properties.

Silica, thus obtained, is a fine white powder, with a harsh feel, and without either taste or smell. Its specific gravity is 2.66. It has no effect on vegetable colours, is insoluble in water, and infusible by the heat of our furnaces. It does not form a ductile paste with water, like alumina. It is found native crystallized, most commonly in hexagonal prisms, terminated by six-sided pyramids.

It does not combine with oxygen, the simple combustibles, simple incombustibles, or the metals. It may be fused with several of the metallic oxides.

The fixed alkalies may be fused with it into glass. Ammonia has no action on it. It may be combined with barytes, strontian, lime, and magnesia, by heat. There is a strong affinity between it and alumina.

Mr Davy has rendered it probable, that silica, like the other earths, is a metallic peroxide. To the metallic basis of it he proposes to give the name of *silicium.*

Chap. I.

Of Oxides.

Oxide explained.

Many bodies, as we have seen already, are capable of combining with oxygen. Now, the compounds into which oxygen enters are of two kinds. They either possess the properties of *acids*, or they are destitute of these properties. To the first class the term *acid* has been applied; to the second that of *oxide*. By *oxide*, then, is meant a combination of oxygen and some other substance destitute of the properties belonging to acids. It is very common to find the same base combine with different doses of oxygen, and form both *acids* and *oxides*. In all these cases, the *smaller* proportion of oxygen constitutes the *oxide*, and the *larger* the *acid*. Hence it follows, that oxides always contain less oxygen than acids with the same base.

The oxides which we have to examine, are combinations of oxygen with the simple combustibles and incombustibles: For the metallic oxides have been already described in the First Book, while treating of the metals. All that is known of the oxides of phosphorus and sulphur has also been stated. We have only to examine in this place, therefore, the oxides of hydrogen, carbon, and azote.

SECT. I. *Of the Oxide of Hydrogen, or Water.*

Oxide of hydrogen.

This well known liquid is found in abundance in every part of the world. When pure, in which state it may be obtained by distillation, it is destitute of colour, taste, and smell.

At the temperature of 40°, a cubic foot of pure water weighs 437102.4946 grains troy, or 999.0914161 ounces avoirdupois. Hence a cubic inch of water at 40° weighs 252.953 grains, and at 60° 252.72 grains. The specific gravity of water is always supposed 1.000, and it is made the measure of the specific gravity of every other body.

When cooled down to 32°, it crystallizes and becomes *ice*. At 212° it boils, and is converted into *steam*, an elastic fluid, invisible like air, and about 1800 times more bulky than water. The boiling point of water is somewhat altered by dissolving salt in it. Some salts raise the boiling point, others lower it a little, while some produce both effects according to the proportion employed.

Water is not altered by heat. It absorbs a little air, and a certain proportion of all gases exposed to it. By long boiling, or by being placed in an exhausted receiver, it is freed from the greatest part of this air.

Water has no action on the simple combustibles while cold; but, at a red heat, charcoal decomposes it. The action of phosphorus is not known. Sulphur, as far as is known, does not decompose it.

Of the metals, iron, zinc, antimony, and tin, decompose it when assisted by heat; silver, gold, copper, and platinum, have no effect on it. The action of the other metals has not been ascertained. The metallic bases of the alkalies and earths decompose it with great rapidity, at the usual temperature of the atmosphere.

Water dissolves the alkalies and alkaline earths. The earths proper are insoluble in it. It dissolves also acids and salts, and is capable of combining with a great variety of bodies. Water unites to bodies two different ways. Some it dissolves, and the compound becomes liquid like water. In this way it dissolves sugar, common salt, and many other bodies. Other bodies combine with it without losing their solidity. The water loses its liquid form, and assumes that of the body with which it unites. In this way it combines with lime, with alumina, with many salts, and with various metallic oxides. When the compound of water with another substance remains liquid, the proportion of water is unlimited; but when the compound formed is solid, the water combines always in a certain determinate proportion. To the first kind of compound, the name of *solution* has been given; to the second, the term *hydrate* has been applied. Thus, *slacked lime* is called *hydrate of lime;* the crystals of barytes and strontian are called *hydrates of barytes and strontian*. Most of the metallic hydrates have lively colours, a strong taste, and are easily soluble in acids; while the oxide which constitutes the base of the hydrate is usually duller in its colour, often tasteless, and always more difficultly soluble in acids. The hydrate of copper is blue, that of nickel and iron green, that of cobalt red, and that of tin white.

All the gases, in their usual state, contain a quantity of water, from which they are best freed by exposure to a very low temperature.

The ancients considered water as an elementary substance. Van Helmont endeavoured to prove, that plants could be nourished by pure water alone, and, of course, that it could be converted into all the substances found in vegetables. Boyle thought that, by long digestion in glass vessels, it could be converted into silica. His experiment was confirmed by Margraff. But Scheele and Lavoisier proved, that the silica was obtained by the decomposition of the glass vessel in which the experiment was made. Mr Cavendish, in 1781, ascertained that water is a compound of oxygen and hydrogen, nearly in the proportion of seven parts of the former, and one of the latter; and this discovery was confirmed by a number of very laborious and rigid experiments.

SECT. II. *Of Carbonic Oxide.*

Carbonic oxide.

The substance at present known by the name of *carbonic oxide*, is a gas which was confounded with carbureted hydrogen, till Dr Priestley drew the attention of chemists to it, in a dissertation which he published in defence of the doctrine of phlogiston. It was examined, in consequence, by Mr Cruikshanks, who showed it to be a compound of *oxygen* and *carbon*, and not of *hydrogen* and *carbon*, as Priestley had supposed. Clement and Desormes also analysed it with the same result.

How obtained.

It may be obtained most readily by mixing together equal weights of iron filings and chalk, each as dry as possible, and exposing them to a red heat in an iron retort. A gas comes over in abundance. It consists partly of *carbonic acid*, partly of *carbonic oxide*. The first gas is removed by washing in lime-water. The carbonic oxide remains behind.

Its properties.

Carbonic oxide is invisible, and possesses the mechanical properties of common air. Its specific gravity is 0.956, that of air being 1.000. No animal can breathe it without death. No combustible substance will burn in it.

It burns with a blue flame, giving out but little light, and is wholly converted into carbonic acid gas. When mixed with oxygen gas, and kindled by means of an electric spark, 100 parts of it require 45 parts by bulk of oxygen gas for complete combustion. The result is about 90 parts of carbonic acid gas. From this experiment it has been deduced, that carbonic oxide is composed of

Composition.

41 carbon.
59 oxygen.
———
100

The simple combustibles have but little action on this gas. Hydrogen has none, even at a red heat, nor charcoal, nor sulphur. But it dissolves a little phosphorus, and acquires the property of burning with a yellow flame.

The simple incombustibles have no effect on it at any temperature tried. Chlorine gradually destroys it over water, converting it into carbonic acid gas. This mixture cannot be kindled by electricity; whereas a mixture of chlorine and carbureted hydrogen burn directly when an electric spark is passed through them.

Its action on metals and their oxides has been but imperfectly examined. Neither the alkalies nor the earths have any action on it whatever.

Sect. III. *Of the Oxides of Azote.*

Oxides of azote.

Azote and oxygen form two different oxides, both gases, and both discovered by Dr Priestley. The first has been called *nitrous acid gas*, the second *nitrous gas*, or *nitric oxide gas*.

1. *Nitrous Oxide Gas.*

Nitrous oxide gas.

This gas was discovered by Dr Priestley in 1776, and called by him *dephlogisticated nitrous gas*. The associated Dutch chemists examined it in 1793, and ascertained its composition. But for the best account of it, we are indebted to Mr Davy.

How obtained.

It may be obtained by exposing the salt called *nitrate of ammonia* in a retort to a heat between 340° and 500°. It melts and emits abundance of gas, which may be collected in jars of water.

Its properties.

Thus obtained, it has all the mechanical properties of air. Its specific gravity is 1.603, that of air being 1.000.

It supports combustion better than common air, almost as well as oxygen gas, but for a much shorter time. But combustibles do not burn in it, unless previously in a state of ignition.

It may be breathed for a short time, and produces effects similar to intoxication.

Water absorbs nearly its own bulk of this gas, and acquires a sweetish taste; but its other properties are not perceptibly altered. It may be driven off from the water unaltered by means of heat.

It is not altered by light, nor by a moderate heat. But by a red heat it is decomposed, and converted into *nitric acid* and *common air*.

Oxygen, or common air, has no action on this gas.

Sulphur, if introduced into this gas while burning with a blue flame, is immediately extinguished; but, if it be burning with a violet flame, it continues to burn for some time with great brilliancy with a fine red flame. The products are sulphuric acid and azote.

Phosphorus, when touched with a wire white hot, burns with great brilliancy in this gas. The products are azotic gas, phosphoric acid, and nitric acid.

Charcoal may be kindled in it by means of a burning glass. The products are carbonic acid gas, and azotic gas.

Hydrogen detonates with it by means of electricity. According to Mr Davy, 39 measures of nitrous oxide consume 40 measures of hydrogen, and after the combustion 41 measures of azotic gas remain. From this experiment it has been concluded, that nitrous oxide is composed by weight of

63 azote.
37 oxygen.
———
100

Composition.

Sulphureted, phosphureted, and carbureted hydrogen gas likewise burn when mixed with nitrous oxide, and kindled.

Neither azote nor muriatic acid produce any effect upon this gas.

Some of the metals, as iron and zinc, burn or may be oxidized in it.

It has the property of combining with alkalies, and of forming a peculiar species of salt, to which the name of *azotites* may be given. Mr Davy, to whom we are indebted for the discovery of these compounds, did not succeed in combining nitrous oxide with ammonia and the earths, but he has rendered it probable that such compounds are possible.

2. *Nitrous Gas.*

Nitrous gas.

This gas was accidentally obtained by Dr Hales; but its properties were first investigated, and its nature ascertained, by Dr Priestley.

How obtained.

To obtain it, dissolve copper or silver in nitric acid diluted with water, a gas separates, which may be collected in jars over water, and is the gas in question.

Its properties.

It possesses the mechanical properties of common air. Its specific gravity is 1.094, that of air being 1.000.

It is exceedingly noxious to animals, producing instant suffocation whenever they attempt to breathe it.

Most combustible substances refuse to burn in it. But pyrophorus burns in it with great splendour; and Homberg's phosphorus takes fire in it spontaneously, just as in common air. Dr Henry has ascertained, that ammoniacal gas, when mixed with it, detonates by means of electricity.

When mixed with common air, or oxygen gas, a yellow colour appears; and if the mixture be standing over water, its bulk gradually diminishes very considerably. The yellow colour is owing to the presence of nitrous acid which is formed, and the diminution of bulk to the gradual absorption of that acid by the water. The cause of this remarkable phenomenon is obvious. The nitrous gas combines with the oxygen, and forms nitrous acid. Hence the diminution of bulk depends upon the quantity of oxygen present. There is a good deal of difference in the result obtained by chemists of the amount of the diminution of bulk which ensues. According to Dalton, 21 measures of oxygen gas unite either with 36 measures of nitrous gas, or with 72 measures. According to Gay-Lussac, 100 measures of oxygen gas unite either with 200 or with 300 measures of nitrous gas, according to circumstances.

Nitrous gas, by electricity, is converted into nitrous acid and azote.

Water, according to Dr Priestley, absorbs about one-tenth its bulk of this gas; according to Dr Henry, about one-twentieth of its bulk.

It is decomposed by phosphorus and charcoal, and probably also by sulphur at a very high temperature. Hydrogen gas mixed with it burns with a green flame. This mixture, according to Fourcroy, detonates when passed through a red-hot tube.

Neither azote nor muriatic acid produce any effect upon it.

Several of the metals decompose it. When kept for some time in contact with iron, its bulk diminishes, and it is converted into nitrous oxide.

It is absorbed unchanged by a solution of green sulphate or muriate of iron. The liquid acquires a deep brown colour, and, when kept, becomes blue. The gas may be expelled unaltered by heat.

The following bodies convert this gas into nitrous oxide. Alkaline sulphites, hydrogureted sulphurets, muriate of tin, sulphureted hydrogen gas, iron or zinc filings moistened with water.

Composition according to Davy.

From the analysis of Mr Davy, it appears to be composed by weight of

57 oxygen.
43 azote.
———
100

Composition according to Gay-Lussac.

According to Gay-Lussac, nitrous gas is composed of equal bulks of oxygen and azotic gas united together, and its specific gravity is exactly the mean. Hence no change of bulk takes place when they are combined. This would give us nitrous gas composed by weight of

53 oxygen.
47 azote.
———
100

Chap. V.

Of Acids.

Acids.

The word *acid*, originally synonymous with *sour*, is at present applied to all bodies possessed of the following properties:

1. When applied to the tongue, they excite that sensation which is called *sour* or *acid*.

2. They change the blue colours of vegetables to red.

3. They unite with water in almost every proportion.

4. They combine with the alkalies, earths, and metallic oxides, and form a class of bodies called *salts*.

Every acid does not possess the whole of these properties. But all of them possess a sufficient number to distinguish them from other bodies. The second and fourth properties are considered as the most important and essential.

It was at one time believed, that there existed only one acid in nature, and that all bodies owed their acidity to the presence of that acid.

This notion was long a favourite one among chemists, and sulphuric and phosphoric acids were pitched upon as the universal acids. But the claims of neither could stand the test of a rigid examination. At last Mr Lavoisier proved, that many substances were capable of combining with *oxygen*, and by that means were converted into acids. Hence oxygen was termed the *acidifying principle*.

All that can be meant by this appellation, is only that many acids contain oxygen as a constituent, and that, when deprived of oxygen, they lose their acid characters. In this sense the appellation is correct enough. But it is not true that oxygen itself possesses acid characters; neither has it been proved that it exists in every acid. Many substances contain oxygen which are entirely destitute of acid properties. Thus water, alkalies, and alkaline earths, contain it. Yet it would be absurd to consider any of these bodies as acids. As the acids are very numerous, and very heterogeneous in their properties, it will be of some importance to subdivide them into classes. They may be arranged under three heads: 1. Acid products; 2. Acid supporters; 3. Combustible acids.

Class I. *Acid Products.*

Acid products.

All the acids belonging to this class possess the following properties:

1. They may be formed by combustion. Of course their base is a simple combustible.

2. They are incombustible.

3. They resist a violent heat without decomposition. But to this there are some exceptions.

4. They are decomposed by the joint action of a combustible body and caloric.

5. Oxygen is an essential ingredient in all of them.

Some of the combustibles combine with two doses of oxygen, and form two distinct acids. When that happens, the acid containing the smallest dose of oxygen is distinguished by the termination *ous*, while that which contains a maximum of oxygen is distinguished by the termination *ic*. Thus *sulphurous* and *sulphuric acids*. The first contains the least, and the second the most oxygen.

Table of acid products, &c.

The following Table exhibits the names of the acid products, their bases, and the proportion of oxygen in each, combined with 100 of the bases as far as it is known at present.

Names.	Bases.	Proportion of Oxygen to 100 Base.
Sulphuric Sulphurous	Sulphur	150 100
Phosphoric Phosphorous	Phosphorus	114.7 58 ?
Carbonic	Carbon	25
Boracic	Boracium	200
Fluoric	Unknown	

Sect. I. *Of Sulphuric Acid.*

Sulphuric acid.

Sulphuric acid seems to have been discovered by the alchymists. It was long obtained by distilling the salt called *green vitriol*, or *sulphate of iron*. Hence the names *oil of vitriol* and *vitriolic acid* originally applied to it. It is now procured by burning a mixture of sulphur and nitre in chambers lined with lead, the bottom of which is covered with wa-

How obtained.

ter. The acid formed is dissolved by the water, and is concentrated by distillation in glass retorts.

Sulphuric acid is liquid, somewhat of an oily consistency, transparent and colourless as water, without any smell, and of a very strong acid taste. It destroys the texture of animal and vegetable substances.

Its properties.

Its specific gravity, when as strong as possible, is about 1.85. It changes all vegetable blues to red, except indigo. When of the specific gravity 1.842, it boils at 546°. When exposed to cold, it crystallizes or congeals. The temperature necessary depends upon the strength. When of the specific gravity 1.780, it freezes at 45°. When stronger or weaker, it requires a much greater degree of cold.

It has a strong attraction for water, and when exposed to the atmosphere, imbibes nearly seven times its weight of that liquid. When the two liquids are mixed together, a considerable heat is evolved. Thus four parts of acid and one of water raises the thermometer to about 300°. The density of this mixture is always considerably greater than the mean. From the experiments of Kirwan, it appears that the strongest sulphuric acid of commerce contains almost 1·5th of water, the remaining 4·5ths are pure acid.

Table of the strength and boiling point of sulphuric acid.

The following Table, drawn up by Mr Dalton from his own experiments, exhibits the strength and the boiling point of sulphuric acid of various densities.

Sp. Gr. of acid.	Real acid per cent. by weight.	Boiling point.
1.850	81	620°
1.849	80	605
1.848	79	590
1.847	78	575
1.845	77	560
1.842	76	545
1.838	75	530
1.833	74	515
1.827	73	501
1.819	72	487
1.810	71	473
1.801	70	460
1.791	69	447
1.780	68	435
1.769	67	422°
1.757	66	410
1.744	65	400
1.730	64	391
1.715	63	382
1.699	62	374
1.684	61	367
1.670	60	360
1.650	58.6	350
1.520	50	290
1.408	40	260
1.30+	30	240
1.200	20	224
1.10—	10	218

Composition.

From the most accurate experiments hitherto made, sulphuric acid appears to be composed of

60 oxygen.
40 sulphur.
———
100

This acid is not altered by exposure to light nor heat. Oxygen gas does not act upon it nor combine with it.

The simple combustibles have but little effect upon it at the ordinary temperature of the atmosphere, but when assisted by heat, they all decompose it. When hydrogen gas and the acid are passed through a red-hot tube, water is formed, and sulphur deposited. Charcoal absorbs oxygen from it, and readily converts it into sulphurous acid, or into sulphur, if the heat be long continued. Phosphorus and boracium produce the same effect. Sulphur, when boiled with it, readily converts it into sulphurous acid.

Azote has no action on it; but it readily absorbs muriatic acid, and forms a smoking compound, which acts powerfully upon some metals.

Sulphuric acid, when concentrated, has little action on the metals. When diluted, it dissolves iron and zinc with rapidity, water is decomposed, and hydrogen gas emitted. When heated, it oxidizes several of the metals, and sulphurous acid is exhaled. On gold and platinum it produces no effect whatever.

It unites readily with the alkalies, earths, and metallic oxides; and forms with them a class of bodies called *sulphates*.

It absorbs a good deal of nitrous gas, and acquires, in consequence, a purplish colour.

This acid is of great importance, both in chemistry and the arts.

SECT. II. *Of Sulphurous Acid.*

Sulphurous acid. How obtained.

The existence of this acid was pointed out by Stahl, but Priestley was the first who procured it in a separate state. It may be obtained by distilling in a retort a mixture of two parts sulphuric acid, and one part of mercury. An effervescence takes place, and a gas comes over, which may be received in jars over mercury.

Its properties.

It is colourless, and possesses the mechanical properties of common air. It has a strong and suffocating odour, precisely the same as that emitted by burning sulphur. Its specific gravity is 2.265, that of air being 1.000. It reddens vegetable blues, and gradually destroys the colour altogether.

When strongly heated, sulphur is deposited, and sulphuric acid formed. When exposed to the temperature of —18°, it is condensed into a liquid.

Water absorbs 33 times its bulk of this gas. The liquid has the smell of the gas, an acid and sulphureous taste, and the specific gravity 1.0513. It may be frozen without parting with the gas. But when heated, the gas is expelled. When this liquid is left to itself, it gradually absorbs oxygen, and the acid is converted into the sulphuric.

Sulphur and phosphorus seem to have no action on this acid; but hydrogen and charcoal decompose it when assisted by heat, and sulphur is evolved. Neither azote nor muriatic acid produce any effect upon it.

It oxidizes and dissolves iron, zinc, and manganese.

It combines with the salifiable bases, and forms salts called *sulphites*.

Sulphuric acid absorbs it, and forms a singular compound called *glasial sulphuric acid*, which readily becomes solid, and smokes when exposed to the air.

Composition.

Its constituents are 50 sulphur,
50 oxygen.
———
100

SECT. III. *Of Phosphoric Acid.*

Phosphoric acid.

This acid was first mentioned by Boyle, but its properties were investigated many years after. It may be obtained by burning phosphorus, or by dissolving phosphorus in nitric acid, and evaporating the liquid to dryness.

How obtained.

Its properties.

In this state it is solid, colourless, and transparent, not unlike glass. It reddens vegetable blues, has no smell, but has a very acid taste. When exposed to the air, it attracts moisture, and gradually runs into an oily-like fluid. Its specific gravity when in the state of glass is 2.8516; when in the liquid state, 1.417.

It is very soluble in water, and is said to be capable of crystallizing, but it is difficult to obtain it in that state.

Oxygen has no effect upon it. None of the simple combustibles are known to be capable of decomposing it, except charcoal. When strongly heated with this substance, phosphorus is disengaged. The simple incombustibles have no effect on it.

It is capable of oxidizing and dissolving some of the metals; but its action on these bodies is by no means strong.

It combines with the salifiable bases, and forms a class of salts called *phosphates*.

Composition.

According to the experiments of Rose, it is composed of

46.5	phosphorus,
53.5	oxygen.
100.0	

Sect. IV. *Of Phosphorous Acid.*

Phosphorous acid.

This acid was known earlier than the preceding. For a long time they were confounded. Lavoisier was, perhaps, the first who accurately distinguished them. It may be obtained by exposing phosphorus to the open air: it gradually absorbs oxygen, and runs into a liquid, which is the acid in question.

How obtained.

Its properties.

It is a viscid colourless liquid, having a very acid taste, and emitting the smell of garlic, especially when heated. It combines with water in any proportion. When evaporated to dryness and heated, it gives out phosphureted hydrogen gas, which burns when it comes in contact with the air. This continues for a long time, and at last the acid is converted into the phosphoric. If nitric acid be poured upon it, this change takes place much more easily and speedily.

The action of the simple combustibles, the incombustibles, and the metals on this acid, is similar to their action on phosphoric acid.

It combines with the different salifiable bases, and forms a class of salts called *phosphites*.

Sulphuric acid, by the assistance of heat, converts it into phosphoric acid.

It has been ascertained that this acid contains less oxygen than the phosphoric, but the actual proportion has not been determined

Sect. V. *Of Carbonic Acid.*

Carbonic acid.

This acid was discovered by Dr Black. Its properties were afterwards investigated by Mr Cavendish and Dr Priestley, and its composition ascertained by Mr Lavoisier. It was at first called *fixed air*. Mr Lavoisier, after ascertaining its base, gave it the name which it now bears. Every chemist almost of eminence, during the last 50 years, has added something to our knowledge of the properties of this remarkable substance.

How obtained.

It may be obtained by burning charcoal, or more easily by pouring muriatic acid on chalk in a glass retort, and receiving the gas which is extricated in glass jars over water. This gas is the acid in question.

Its properties.

It is invisible, and possesses the mechanical properties of air. No combustible will burn in it. It is unfit for respiration. It affects the nostrils with a kind of pungent sensation, but when diluted with air, it has no smell whatever. Its specific gravity is 1.500, that of air being 1.000. It reddens very delicate vegetable blues.

Atmospheric air contains about $\frac{1}{1000}$ of its bulk of this gas.

It is not altered by passing it through a red hot tube; but when electric sparks are passed through it for a long time, its bulk increases, and a portion of carbonic oxide is evolved.

Water absorbs it when placed in contact with it. The rapidity of the absorption is much increased by agitation. Water absorbs its own bulk of this gas at the temperature of 41°. The water acquires a sour taste, a sparkling appearance, and the property of reddening vegetable blues. When heated or frozen, the gas is extricated. It makes its escape also if the liquid be left exposed to the open air.

Carbonic acid is not acted upon by oxygen, nor, as far as is known, is it altered by any of the simple combustibles, incombustibles, or metals. But several of these bodies, as charcoal, phosphorus and different metals, have the property of decomposing it at a red heat, when it is in combination with lime, barytes, or strontian. In these cases a quantity of carbonic oxide is usually evolved.

It combines with the salifiable bases, and forms a class of salts called *carbonates*.

Composition.

From the most exact experiments hitherto made, we may consider this acid as composed very nearly of

28	carbon.
72	oxygen.
100	

Sect. VI. *Of Boracic Acid.*

Boracic acid.

This acid is obtained from the salt called *borax*, brought to Europe from the East, where it is found chiefly at the bottom of some lakes in Thibet and China. It was first extracted from borax by Homberg, and its nature was ascertained by Baron. To obtain it, dissolve borax in hot water, and add sulphuric acid till the liquid assumes a sensibly acid taste. As the liquid cools, it deposites white crystalline scales, which are *boracic acid*.

How obtained.

Its properties.

Thus obtained, it has the form of thin hexagonal scales of a silvery whiteness. Its taste is sourish and bitterish. It has no smell. It reddens vegetable blues. Its specific gravity, while in scales, is 1.479, when melted 1.803.

It is not altered by light nor heat. In a red heat it melts into a transparent colourless glass, which becomes somewhat opake when exposed to the air, but does not attract moisture.

Boiling water does not dissolve more than 0.02 of this acid, and cold water still less.

Neither oxygen, the simple combustibles, incombustibles, or metals, produce any effect upon this acid. But when heated with potassium it is decomposed, and its base *boracium* separated.

Composition.

From the experiments of Davy, we may conclude that boracic acid is composed of about

33	boracium.
67	oxygen.
100	

It is soluble in alcohol, and alcohol containing it burns with a green coloured flame. It dissolves also in some of the oils.

It is hardly capable of oxidizing any of the metals except iron and zinc.

It combines with the salifiable bases, and forms a class of salts called *borates*.

SECT. VII. *Of Fluoric Acid.*

Fluoric acid.

This acid was discovered by Scheele. He obtained it from a pretty common and beautiful mineral called *fluor spar*, and in this country often Derbyshire spar. This mineral is a compound of fluoric acid and lime. Dr Priestley first obtained the acid in a separate state.

How obtained.

To procure this acid, pour sulphuric acid on the pounded spar, and apply heat. A gas comes over, which must be received over mercury. It is the acid in question.

Its properties.

This gas possesses the mechanical properties of air. It does not support combustion, nor can animals breathe it. It smokes when mixed with the atmosphere, and has a smell similar to that of muriatic acid.

It is not altered by exposure to heat or light.

Water absorbs it rapidly. If glass vessels have been employed to procure it, a jelly is deposited as soon as it comes in contact with the water. This jelly consists of silica, which the gas has dissolved from the glass, and which it held in solution. No method has been yet discovered of obtaining fluoric acid gas free from foreign matter. If leaden vessels be used, the gas does not assume the elastic form, at least we could not procure it by means of these vessels. When fluor spar and vitreous boracic acid are heated together, a gas is obtained, which is a combination of the two acids, to which Thenard and Gay-Lussac, who discovered this compound gas, have given the name of *fluoboracic* acid gas.

Neither oxygen, the simple combustibles, incombustibles, or metals, as far as is known, produce any effect upon this gas. It does not act powerfully upon the metals.

The fluoboracic acid is absorbed by water, and forms a very powerful acid liquid, nearly as heavy as sulphuric acid, and capable of resisting as strong a heat before it is volatilized.

One of the most curious properties of fluoric acid is the ease with which it corrodes glass, when that substance is exposed to its fumes. In consequence of this property, it has been employed to etch upon glass.

It combines with the different bases, and forms a class of salts called *fluates*.

All attempts to decompose this acid have failed, in consequence chiefly of the impossibility of making experiments on it in a state of purity.

CLASS II. *Acid Supporters.*

Acid supporters. Their properties.

The acid supporters are distinguished by the following properties:

1. They cannot be produced by combustion. Hence their base is either a simple incombustible or a metal.

2. They support combustion. Hence they acidify the combustible bases, and oxidize the metals.

3. They are decomposed at a high temperature, their oxygen making its escape in the state of gas.

The only acid supporters known at present, are those which have the simple incombustibles and arsenic for their bases. From analogy, we refer the whole of the metallic acids to this head.

Table of acid supporters, &c.

The following Table exhibits a view of all the acid supporters, of their bases, and of the proportion of their constituents, as far as that has been ascertained.

Names.	Bases.	Proportion of Oxygen to 100 base.
Nitric Nitrous	Azote	236
Arsenic	Arsenic	53
Tungstic	Tungsten	25
Molybdic	Molybdenum	50
Chromic	Chromium	200
Columbic	Columbium	

Oxygen is an essential constituent of all these acids, as well as of those belonging to the first class.

SECT. I. *Of Nitric Acid.*

Nitric acid.

This acid seems to have been first obtained in a separate state by Raymond Lully, one of the most celebrated of the alchymists. It was called at first *water of nitre*, *aqua fortis*, *spirit of nitre*.

How obtained.

It may be obtained, by distilling a mixture of three parts nitre and one of sulphuric acid in a glass retort.

Its properties.

The acid thus obtained has a yellow colour; but, if kept for a short time in a boiling heat, it becomes colourless. It has a peculiar smell, it smokes when exposed to the atmosphere. Its taste is extremely acid, and it is one of the most corrosive substances known, tinging the skin instantly of an indelible yellow, and very soon destroying its texture entirely. It converts vegetable blues to red. Its specific gravity when strongest never exceeds 1.583. It contains mixed with it a considerable portion of water, from which it cannot be freed. When strongest, this water amounts to about one-fifth of the whole.

Table of the strength and boiling point of nitric acid.

The following Table, by Mr Dalton, exhibits the strength and boiling point of this acid when of various densities.

Specific gravity of acid.	Real acid per cent. by weight.	Boiling point.
1.62	82.7	
1.54	72.5	175°
1.50	68	210
1.45	58.4	210
1.42	54.4	248
1.40	51.2	247
1.35	44.3	242
1.30	37.4	236
1.26	32 3	232
1.22	28.5	229
1.20	25.4	226
1.18	23	223
1.17	21	221
1.16	19.3	220
1.15	17.8	219
1.14	16.6	219

When of the specific gravity 1.42 it boils at 248°, and may be distilled over without alteration. When cooled sufficiently it congeals, and the freezing point varies exceedingly according to the strength of the acid. There is a certain strength at which it congeals most easily, and, if it be either stronger or weaker, the freezing point is considerably lower.

Oxygen has no effect upon this acid; but all the simple combustibles decompose it. When poured upon charcoal, phosphorus, or sulphur, at a high temperature, it sets them on fire. When diluted, it effervesces with these bodies, and acidifies them. Hydrogen gas does not act upon it at the common temperature of the atmosphere, but when passed with it through a red hot tube, it detonates, water is formed, and azotic gas disengaged. Boracium is readily converted by it into boracic acid. When poured upon the volatile oils, and even upon several of the fixed oils, it sets them on fire. If it be previously mixed with a little sulphuric acid, it sets almost all the oils on fire.

Azote has no action on this acid, but muriatic acid forms with it the compound called *aqua regia*, or *nitro-muriatic acid.*

It is capable of oxidizing all the metals, except gold, platinum, and titanium. With most of the oxides it combines, though some, as the peroxides of tin and antimony, are insoluble in it. It even sets fire to some of the metals, when poured upon them in fusion.

It absorbs nitrous gas in great abundance, and becomes first yellow, then orange, then olive, and at last green, according to the proportion of gas present. Acid thus contaminated with nitrous gas was formerly called *dephlogisticated nitric acid*, and *nitrous acid;* on the supposition that it was nitric acid deprived of a portion of its oxygen. When fully saturated with nitrous gas, it assumes a gaseous state, and is known by the name of gaseous vapour.

Nitric acid combines with the different salifiable bases, and forms a class of salts called nitrates.

Composition.

It has been ascertained, that this acid is a compound of oxygen and azote in the following proportions.

29.77 azote.
70.23 oxygen.
100.00

Sect. II. *Of Nitrous Acid.*

Nitrous acid.

When *nitre*, which is a compound of nitric acid and potash, is exposed to a red heat, it yields a considerable portion of oxygen gas. If the process be conducted with the proper precautions, and stopped in time, the nitre still retains the properties of a neutral salt. But the acid which it contains is obviously in a different state, since it has lost a considerable part of its oxygen. To this new state the term *nitrous acid* is applied.

In this state it was discovered by Scheele, but all attempts to obtain the acid by itself have failed. It is decomposed apparently whenever it is separated from the potash; for fumes of nitrous gas immediately make their appearance.

Sect. III. *Of Arsenic Acid.*

Arsenic acid.

This acid was discovered by Scheele. It may be formed in the following manner: Mix in a retort one part of muriatic acid, four parts of white oxide of arsenic, and 12 parts of nitric acid of the specific gravity 1.25. Boil the mixture till the oxide disappear, and nitrous fumes cease to be disengaged; then evaporate to dryness, and expose the mass to a low red heat. The matter thus obtained is solid *arsenic acid.*

How obtained.

Its properties.

It is a white solid mass nearly tasteless, of the specific gravity 3.391. It is very fixed. It melts at a red heat, and is converted into glass.

It dissolves slowly in cold, but rapidly in hot water, and by cautious evaporation may be obtained in crystals. The taste of the solution is acid, caustic, and metallic.

Oxygen has no effect on it. The simple combustibles decompose it when assisted by heat, and sometimes take fire, in consequence of its action on them, a proof that this acid is a supporter of combustion.

The simple incombustibles have no action on it. It oxidizes several of the metals, especially when assisted by heat.

It combines with the salifiable bases, and forms a class of salts called *arseniates.*

It has no action on any of the acids already described.

Composition.

From the analysis of Proust, it appears that this acid is composed of

65 arsenic.
35 oxygen.
100

Sect. IV. *Tungstic Acid.*

Tungstic acid.

The substance originally called tungstic acid, was discovered by Scheele. It was not pure, being contaminated by the acid employed in separating it.

The real tungstic acid is a yellow powder, first described by the Eluyarts. It is tasteless, insoluble in water, and has no effect on vegetable blues. It is rather an oxide than an acid. But it combines with the salifiable bases, and forms a class of salts called *tungstates*.

Sect. V. *Of Molybdic Acid.*

Molybdic acid.

This acid was discovered by Scheele. It has been lately examined by Bucholz.

How obtained.

It may be obtained by digesting nitric acid on molybdena, till the whole is converted into a white mass. Edulcorate this mass with water, the residue is molybdic acid.

It is a white powder of the specific gravity 3.460. In close vessels it melts and crystallizes when heated; but in open vessels it sublimes, and may be collected in the form of brilliant yellow scales.

Its properties.

It is soluble in 960 parts of water. The solution is pale yellow. It is tasteless, but reddens vegetable blues.

Molybdic acid is not affected by oxygen gas; but it is decomposed by sulphur and charcoal, and several of the metals.

It combines with the salifiable bases, and forms a class of salts called *molybdates*.

It dissolves in sulphuric acid. The solution is colourless when hot, but becomes blue when cold. It dissolves also in muriatic acid, but not in nitric acid.

Composition.

According to the analysis of Bucholz, it is composed of

67 molybdenum.
33 oxygen.
———
100

Sect. VI. *Of Chromic Acid.*

Chromic acid.

This acid was discovered by Vauquelin. It may be obtained from the *red lead ore* of Siberia, by boiling the ore with carbonate of soda, decanting off the fluid solution, and saturating it with sulphuric acid. A red powder falls, which is *chromic acid*.

How obtained.

Its properties.

It has a red or orange yellow colour, an acrid and metallic taste; is soluble in water, and crystallizes in elongated prisms of a ruby colour.

When heated it gives out oxygen gas, and is converted into green oxide of chromium.

When mixed with filings of tin and muriatic acid, it becomes at first yellowish brown, and afterwards assumes a beautiful green colour. When treated with acids, and various other combustibles, a green colour is also evolved.

Sect. VII. *Of Columbic Acid.*

Columbic acid.

This acid was discovered by Hatchet in an ore from America of a black colour, which he found in the British Museum. It was obtained by fusing the ore with potash, dissolving the potash in water, and adding nitric acid to the solution. The columbic acid precipitated in flakes.

How obtained.

Its properties.

It is a powder of a white colour, and not very heavy. It is tasteless, insoluble in water, but gives a red colour to vegetable blues.

Sulphuric acid dissolves it, and forms a colourless solution, from which the columbic acid is precipitated by water. It is soluble also in muriatic acid, but not in nitric acid.

It combines with the salifiable bases, and forms a class of salts called *columbates*.

Class III. *Combustible Acids.*

Combustible acids.

The acids belonging to this class may be distinguished by the following properties.

Their properties.

1. If they be combined with potash, and distilled, they are decomposed, charcoal is usually evolved, and a considerable quantity of heavy inflammable air extricated.

2. All of them contain at least two simple combustibles as a base, namely *carbon* and *hydrogen*. Some of them also contain *azote*. Oxygen usually enters into their composition, though not perhaps always.

3. They do not seem capable of combining with different doses of oxygen. Whenever the proportion of oxygen changes, that of the other constituents varies also.

4. They are decomposed by the action of the more powerful acid supporters, and either converted into other combustible acids, or into oxide and acid products.

They may be divided into four orders. Those belonging to the first crystallize, and may be volatilized without decomposition. Those belonging to the second likewise crystallize, but they cannot be volatilized without decomposition. Those belonging to the third order are not crystallizable, though they may be exhibited in the state of a dry mass. Under the fourth order are placed three acids, which, from the singularity of their properties, ought to be considered apart.

The following Table exhibits the names and component parts of each of these acids, as far as is known at present.

Order I. *Crystallizable, volatilizable.*

Names.	Constituents.
1. Acetic.	Carbon, hydrogen, oxygen.
2. Benzoic.	
3. Sebacic.	
4. Succinic.	
5. Moroxylic.	
6. Camphoric.	
7. Oxalic?	

ORDER II. *Crystallizable, not volatilizable.*

Names.	Constituents.
1. Mellitic.	Carbon, hydrogen, oxygen.
2. Tartaric.	
3. Citric.	
4. Kinic.	
5. Saclactic.	
6. Uric.	Carbon, hydrogen, azote, oxygen.

ORDER III. *Not crystallizable.*

1. Malic.	Carbon, hydrogen, oxygen.
2. Suberic.	
3. Formic.	

ORDER IV. *Colorific.*

1. Prussic.	Carbon, hydrogen, azote.
2. Gallic.	Carbon, hydrogen, oxygen.
3. Tannin.	

SECT. I. *Of Acetic Acid.*

Acetic acid.

How obtained.

This has been the longest known of all the acids. It is obtained by causing *wine* or *beer* to undergo a new fermentation. They become sour, and are known by the name of *vinegar*. When the vinegar is distilled, a transparent colourless liquid is obtained, called *distilled vinegar*, or sometimes *acetous acid*. When this substance is combined with oxide of copper, and the dry mass distilled, a liquid is obtained, which contains the acid in a much more concentrated state. It was formerly called *radical vinegar*, and *acetic acid*, by way of eminence.

It is now known that the acid principle in all these three liquids is precisely the same, and that they differ merely in the concentration of that acid, or in consequence of containing small quantities of some foreign ingredient. Hence, the term *acetic acid* is now applied to the acid in all cases.

Its properties.

Acetic acid is a liquid, transparent and colourless like water. It has a peculiar and well known aromatic smell, when in the state of vinegar or distilled vinegar. In radical vinegar this smell is not so agreeable, being mixed with a kind of empyreumatic odour. When sufficiently concentrated, it may be obtained in crystals; but the process is difficult, and requires particular precautions to ensure success.

The specific gravity of distilled vinegar varies from 1.007 to 1.0095: that of radical vinegar is 1.080. But the strength of the acid is not always proportional to its specific gravity, owing to the presence of foreign bodies, from which it is very difficult to free it. It is very volatile, unites with water in any proportion, and reddens vegetable blues.

Neither oxygen, the simple combustibles, or incombustibles, have any action on this acid. It oxidizes some metals; but its action on these bodies is not violent. It combines with metallic oxides, and forms with every one a soluble salt. Indeed all the salts that contain acetic acid are soluble in water. In this respect it agrees with nitric acid.

It combines with salifiable bases, and forms a class of salts called *acetates*.

Sulphuric and nitric acids seem capable of decomposing it, but the action of the other acids is not remarkable. It dissolves and combines with many vegetable bodies, and is, in consequence, useful in vegetable analysis.

Composition.

It is composed of oxygen, hydrogen, and carbon, according to the experiments of Thenard and Gay-Lussac, in the following proportions:

Oxygen,	44.147
Hydrogen,	5.629
Carbon,	50.224
	100

SECT. II. *Of Benzoic Acid.*

Benzoic acid.

This acid is obtained, by sublimation, from a resinous substance called benzoin.

Its properties.

It is a fine light white matter in small needles. It is not brittle, but has a kind of ductility. Its taste is acrid, hot, and somewhat bitter. Its odour is weak but aromatic. Its specific gravity is 0.667. It reddens the most delicate vegetable blues.

It is easily volatilized by heat. It burns when kindled, and leaves no residuum. It is not altered by exposure to the air. Cold water dissolves no sensible quantity of it, but it dissolves readily in hot water.

It is not acted upon by oxygen gas, or by any of the simple combustibles or incombustibles; nor does it seem capable of oxidizing any of the metals.

It combines with the salifiable bases, and forms a class of salts called *benzoates*.

Several of the strong acids dissolve it; but it is precipitated again unaltered by the infusion of water. Alcohol dissolves it copiously.

SECT. III. *Of Sebacic Acid.*

Sebacic acid.

This acid was mentioned many years ago, but its nature and properties remained unknown till it was lately examined by Thenard. Berzelius has lately added considerably to our knowledge of it. It may be prepared by the following process.

How prepared.

Distil hog's lard; wash the product with hot water, separate this water and drop into it acetate of lead. A flaky precipitate appears which is to be washed and dried, mixed with sulphuric acid and heated. A melted substance, like fat, swims on the surface. This substance is sebacic acid.

Its properties.

Sebacic acid is white; it has no smell; its taste is a pleasant sour, leaving in the mouth a very slight impression of bitterness. It reddens vegetable blues. When heated, it melts like tallow, and, on cooling, concretes into a crystallized mass. It may be volatilized, but requires a higher temperature than benzoic acid. Berzelius has shown that this acid, in most of its properties, coincides with benzoic acid; and that the two acids, if not absolutely the same, at least approach very closely to each other.

Sect. IV. *Of Succinic Acid.*

Succinic acid.
How obtained.

This acid is obtained when amber is exposed to heat. It sublimes in small needles, coloured by an oil, from which it may be freed by digestion in nitric acid and subsequent crystallization. Trommsdorf affirms, that when dry saclactic acid is distilled, it yields abundance of succinic acid.

Its properties.

This acid is white, crystallizes in triangular prisms, has an acid taste, and reddens vegetable blues. When heated, it melts and then sublimes.

It is but little soluble in cold, but very soluble in hot water. Alcohol acts nearly upon it as water. It dissolves in sulphuric, nitric, and muriatic acids, without undergoing decomposition.

It combines with the salifiable bases, and forms a class of salts called *succinates*.

Sect. V. *Of Moroxylic Acid.*

Moroxylic acid.

This acid was discovered by Klaproth in a saline exudation incrusting the bark of the white mulberry tree. This salt was a compound of the acid in question and lime.

How obtained.

The acid was separated by dissolving the salt in water, and precipitating the acid by means of acetate of lead. The precipitate was mixed with diluted sulphuric acid and digested. Sulphate of lead was formed, and moroxylic acid disengaged.

Its properties.

It crystallized in needles, which had the taste of succinic acid, were not altered by exposure to the air, and dissolved readily in water and in alcohol. When heated it sublimes, and thus may be obtained quite pure.

Sect. VI. *Of Camphoric Acid.*

Camphoric acid.

This acid was discovered by Kozegarten, but first accurately described by Bouillon La Grange.

How obtained.

It is obtained by distilling a solution of camphor in nitric acid, repeatedly adding nitric acid till it amounts to 24 times the weight of the camphor. Crystals gradually make their appearance, which consist of *camphoric acid*.

Its properties.

This acid is snow-white. Its crystals are parallelopipeds which effloresce in the air. Its taste is acid and bitter, it has the smell of saffron, and reddens vegetable blues.

It dissolves in about 100 parts of cold water, but is more soluble in hot water. It dissolves in alcohol. The salts which it forms are called *camphorates*.

Sect. VII. *Of Oxalic Acid.*

Oxalic acid.
How obtained.

This acid was discovered by Scheele, and first described by Bergman. It is obtained by heating a solution of sugar in nitric acid.

Its properties.

It crystallizes in small four-sided prisms, terminated by dihedral summits. These crystals are composed of 77 parts acid, and 23 water. When exposed to heat, it sublimes, but at the same time is partly decomposed.

These crystals have a very acid taste, and redden vegetable blues. They dissolve in their own weight of boiling water, and in twice their weight of cold water. They dissolve, also, readily in alcohol.

When exposed to dry air, they effloresce; but in moist air, they are not altered. Neither oxygen, nor the simple combustibles or incombustibles act on this acid. It oxidizes some of the metals; but most of them are not affected by it.

It combines with the salifiable bases, and forms a class of salts called *oxalates*.

Muriatic and acetic acids dissolve it; sulphuric acid decomposes it, by the assistance of heat. Nitric acid converts it into water and carbonic acid.

Composition, according to Dr Thomson.

When combined with a base and distilled, it is decomposed, and converted into *water*, *carbonic acid*, *carbonic oxide*, *carbureted hydrogen*, and *charcoal*. It is composed, according to the experiments of Dr Thomson, of

oxygen,	64
carbon,	32
hydrogen,	4
	100

According to Thenard and Gay-Lussac.

Thenard and Gay-Lussac make its constituents as follows:

oxygen,	70.689
carbon,	26.566
hydrogen,	2.745
	100

Sect. VIII. *Of Mellitic Acid.*

Mellitic acid.

This acid was discovered by Klaproth, in the mineral called *mellite* or *honeystone*, which he found composed of alumina and the acid in question.

How obtained.

It is obtained by boiling the mineral powder in 72 times its weight of water, filtering the liquid, and evaporating sufficiently. The mellitic acid crystallizes.

Its properties.

The crystals are needles, having a brownish colour, and a sweetish sour taste. It is but moderately soluble in water. Nitric acid does not seem to decompose it. It reddens vegetable blues. The salts which it forms are called *mellates*.

Sect. IX. *Of Tartaric Acid.*

Tartaric acid.

This acid exists in the salt called *tartar*, from which it was first obtained in a separate state by Scheele. The process is this:

How obtained.

Dissolve tartar in water, and add chalk in powder as long as an effervescence continues. A white powder precipitates. Pour on this precipitate a quantity of sulphuric acid equal in weight to the chalk employed, previously diluted with water, and digest for a day or two. Then filter and evaporate the liquid. The tartaric acid is obtained in crystals.

These crystals are white, transparent, and hard. They are very irregular four-sided prisms, composed of 84.5 real acid, and 15.5 water.

Its properties.

It is not altered by exposure to the air. At 212°, it melts and becomes as liquid as water. At 250°, it boils without losing its transparency or acquiring colour. When cooled, it concretes into a hard mass, but the nature of the acid is changed. It has now acquired the property of deliquescing when exposed to the air. When distilled, this acid yields an acid liquid formerly called pyrotartarous acid, but now known to be the acetic disguised by means of an empyreumatic oil. When combined with a base and distilled, tartaric acid is decomposed, and converted into *water*, *carbonic acid*, *heavy inflammable air*, and *charcoal*.

It dissolves readily in water, and when the solution is diluted, the acid undergoes spontaneous decomposition.

None of the simple substances produce any striking effect upon this acid. It combines with the salifiable bases, and forms a class of salts called *tartrates*.

Composition.

According to Thenard and Gay-Lussac, it is composed of

Oxygen,	69.321
Carbon,	24.050
Hydrogen,	6.629
	100

SECT. X. *Of Citric Acid.*

Citric acid.

This acid exists in the juice of oranges and lemons, and was first obtained pure by Scheele. His process was this:

How obtained.

Saturate lemon-juice with chalk. A precipitate falls. Wash this precipitate, and pour on it as much sulphuric acid as will saturate the chalk employed, previously diluted with six times its weight of water. Digest, filter, and evaporate the liquid. The citric acid crystallizes.

Its properties.

This acid crystallizes in rhomboidal prisms. The crystals are not altered by exposure to the air. The taste is acid, and vegetable blues are reddened by it. It dissolves in less than its weight of water.

It is not acted on by the simple substances. It oxidizes a few of the metals. It combines with the salifiable bases, and forms a class of salts called *citrates*.

Sulphuric acid decomposes it. Nitric acid converts it into oxalic acid, or into acetic acid, if used in excess.

Composition.

Its constituents, according to Thenard and Gay-Lussac, are as follows:

Oxygen,	59.859
Carbon,	33.811
Hydrogen,	6.330
	100

SECT. XI. *Of Kinic Acid.*

Kinic acid.

This acid was discovered by Vauquelin, in a salt first obtained from *Jesuits bark*, by Deschamps. This salt is a compound of kinic acid and lime.

How obtained.

Vauquelin dissolved the salt in water, and precipitated the lime by means of oxalic acid. The liquid was evaporated to the consistence of a syrup, and then set aside. No crystals formed in it at first, but on being touched, it wholly crystallized in diverging plates.

Its properties.

Its colour is somewhat brown, its taste very acid and bitter. It was not altered by exposure to the air. It is very soluble in water. It does not precipitate silver nor lead from their solutions. When heated, it is decomposed, and charcoal remains behind.

SECT. XII. *Of Saclactic Acid.*

Saclactic acid.

How obtained.

This acid was discovered by Scheele, who formed it by digesting sugar of milk in nitric acid. Fourcroy and Vauquelin ascertained, afterwards, that it is formed when gum is heated with nitric acid and the solution allowed to cool. A white powder precipitates, which is the acid in question.

Its properties.

Saclactic acid, thus obtained, is in the form of a white gritty powder, with a slight acid taste. It is only slightly soluble in boiling water. The solution has an acid taste, and reddens vegetable blues.

The compounds which this acid forms with the salifiable bases, are called *saccolates*.

Composition.

The constituents, according to Thenard and Gay-Lussac, are as follows:

Oxygen,	62.69
Carbon,	33.69
Hydrogen,	3.62
	100

SECT. XIII. *Of Uric Acid.*

Uric acid.

This acid was discovered by Scheele in urinary calculi, and first called *lithic acid*. But this term was afterwards laid aside, and *uric acid* substituted; because this acid constitutes one of the ingredients of urine. For the best account of the properties of this acid, we are indebted to Dr Henry.

How obtained.

It is obtained by dissolving the calculi, composed chiefly of it, in alkaline ley, and precipitating by means of muriatic or acetic acids. The white powder which falls, when well edulcorated, is pure uric acid.

Its properties.

It is a white powder, without taste or smell. It reddens vegetable blues, and requires more than 1700 parts of cold water to dissolve it.

It dissolves readily in fixed alkaline solutions, but not in alkaline carbonates. It dissolves in nitric acid; and when the solution is evaporated nearly to dryness, it assumes a fine pink colour, which becomes much deeper when water is added, so as to have a near resemblance to carmine. The watery solution of this matter loses its red colour in a few hours, and it cannot afterwards be restored.

Oxymuriatic acid readily converts the uric into the oxalic acid.

When distilled, carbonate of ammonia is obtained, and a saline sublimate, which Dr Henry has shown to be a compound of ammonia with a peculiar acid.

SECT. XIV. *Of Malic Acid.*

Malic acid.

This acid was discovered by Scheele. It exists in apples, and in a variety of vegetable substances. It is formed also by the action of nitric acid on sugar.

How obtained.

Scheele obtained it by saturating the juice of apples with potash, precipitating by acetite of lead, digesting the precipitate in a sufficient quantity of sulphuric acid to separate the lead, and then filtrating. The liquid contained pure malic acid.

When malic acid is obtained by the action of nitric acid on sugar, it is colourless; but it very easily acquires a brown colour by the action of heat, or even by keeping it in a liquid state. When evaporated, it may be obtained in a solid state; but it is not capable of crystallizing.

Its properties.

Its taste is very acid, and it dissolves readily in water. It is said to undergo spontaneous decomposition; but we have kept it more than two years in a liquid state without observing any such change. It bears a strong resemblance to the citric acid, but it does not crystallize; forms a more soluble salt with lime; and precipitates mercury, lead, and silver, from nitric acid, which citric acid does not.

The compounds which it forms with the salifiable bases, are called *malates*.

SECT. XV. *Of Suberic Acid.*

Suberic acid.

This acid was obtained by Brugnatelli by digesting common cork in nitric acid. Its properties were afterwards more investigated by Bouillon La Grange.

Its properties.

It does not crystallize, but may be obtained in powder or in pellicles. Its taste is acrid and slightly bitter; it reddens vegetable blues, attracts moisture when exposed to the air, but is not very soluble in water. It may be sublimed without decomposition. The other acids dissolve it incompletely. The salts which it forms are called *suberates*.

SECT. XVI. *Of Formic Acid.*

Formic acid.

This acid exists in the *formica rufa*, or *red ant*. It was noticed in a paper by Mr Ray in 1671, in consequence of the observations of Halse and Fisher. But its properties were first investigated by Margraff. Fourcroy and Vauquelin endeavoured to prove that it was a mixture of *acetic* and *malic acids*; but the experiments of Suersen have shewn that this opinion is not correct.

How obtained.

This acid may be obtained by infusing the ants in water, distilling off the water as long as it comes over without any burnt smell, saturating the water with potash, evaporating to dryness, mixing the residue with as much diluted sulphuric acid as is sufficient to saturate the potash employed, distilling this mixture to dryness, rectifying the liquid that comes over by a second distillation with a moderate heat. The liquid now contains only pure formic acid.

Its properties.

This liquid is colourless like water. It has a peculiar smell; it reddens vegetable blues, and has an acid taste. Its specific gravity varies from 1.102 to 1.113, whereas the most concentrated acetic acid is only 1.080 Notwithstanding this superior weight, it is not capable of neutralizing so much of the salifiable bases as acetic acid. Lowitz attempted, in vain, to procure this acid in crystals, though he succeeded easily with acetic acid. The compounds which it forms with the different bases are called *formates*. There is a striking analogy between them and the *acetates*.

CHAP. VI.

Of Colorific Acids.

Colorific acids.

UNDER this name we include three substances, which possess such peculiar properties that they ought to be considered separately from the combustible acids. These are *prussic acid*, *gallic acid*, and *tannin*. The two first have always been considered as acids. The last, though not acid, is so intimately connected with the gallic, that they cannot well be separated. These substances possess the following characters.

1. They unite with alkaline bodies, but do not seem capable of neutralizing them.

2. They act with great energy upon metallic solutions, usually entering into combination with the oxide, and precipitating it in the state of an insoluble powder.

3. They have a tendency to enter into triple compounds with a variety of bodies, especially with metallic oxides and alkalies.

SECT. I. *Of Prussic Acid.*

Prussic acid.

This important substance was accidentally discovered by a chemist of Berlin in 1710. This chemist, Diesbach by name, found out the method of preparing *Prussian blue*. The nature of this pigment was examined by Brown. But it was Macquer who first ascertained its nature in a satisfactory manner. In consequence of his experiments, Prussian blue was considered as a compound of oxide of iron, with a peculiar acid. But no one was able to obtain this acid in a separate state, or to ascertain its properties, till Scheele, in two admirable dissertations published in 1782 and 1783, pointed out a method of procuring it, and gave a detailed account of its nature.

How obtained.

He procured the Prussic acid in the following manner: He boiled in a matrass a mixture of 10 parts Prussian blue, 5 parts red oxide of mercury, and 30 parts of water, and filtered the solution. The liquid was poured upon 2¼ parts of clean iron filings, and at the same time 1 part of sulphuric acid was added, and the mixture shaken. The iron disappeared, and a quantity of running mercury was precipitated in its place. Distil off one-fourth of this liquid by a moderate heat, what comes over consists of water holding prussic acid in solution.

Its properties.

Prussic acid, thus obtained, is a colourless liquid like water. It has a strong odour, resembling that of the flowers of the peach or of bitter almonds. Its taste is sweetish, acrid, and hot, and it is apt to excite cough. It does not alter the colour of vegetable blues. When swallowed, it proves a very virulent poison.

How obtained pure.

In this state it is combined with water; but Gay-Lussac obtained it pure by the following process: He put into a tubulated retort a quantity of prussiate of potash, and poured over it weakly fuming muriatic acid. The retort was luted to a flask containing a mixture of chalk and muriate of lime in powder. This flask communicated with a second containing muriate of lime, and this with a third empty. The flasks were surrounded with a mixture of two parts snow, and one part salt. A gentle heat being applied to the retort, the prussic acid passed over, and swam above the muriate of lime. By gently heating the first flask, the acid is made to pass into the second flask, and by this means is rectified.

Its properties.

Prussic acid, thus obtained, is a limpid and colourless liquid. It is extremely volatile and pungent; boiling at the temperature of 80°, and at the temperature of 50° it supports a column of mercury rather more than ten inches high. At 68° it quintuples the bulk of any gas with which it is mixed. It freezes at 2°. In consequence of this extreme volatility and easy congelation, a curious phenomenon takes place. If a drop of it be let fall upon a sheet of paper, it immediately freezes, in consequence of rapid evaporation. The specific gravity of this liquid is 0.70583 at the temperature of 44.5°. It reddens vegetable blues.

It is capable, when dry, of withstanding a red heat without decomposition; but when water is present, it very readily undergoes change.

It combines with the salifiable bases, and forms a class of bodies called *prussiates*. But they have very little permanency, being decomposed by all other acids, and even by exposure to the atmosphere.

It is also capable of forming triple compounds, in which it is combined with two bases at once, one of them an alkali or earth, the other a metallic oxide. These compounds are much more permanent, and are therefore usually employed by chemists. The one in most frequent use is the *triple prussiate of potash*, a yellow coloured salt crystallizing in cubes, and composed of prussic acid, potash, and oxide of iron.

Scheele's method of forming Prussic acid.

Scheele succeeded in forming prussic acid, by causing a current of ammoniacal gas to pass through red hot charcoal; and the experiment has been since repeated successfully by others. Hence it is obvious, that this acid is composed of the constituents of ammonia and charcoal united together, or of hydrogen, azote, and carbon. This has been further confirmed by Berthollet. Chlorine has the property of altering the nature of prussic acid, and renders it capable of throwing down iron from solutions *green* instead of blue. To the acid thus altered, Berthollet gave the name of *oxyprussic acid*. When heat is applied to it, the whole is converted into carbonate of ammonia.

Prussian blue.

Prussian blue may be formed, by calcining a mixture of potash and dried blood in a covered crucible, in a heat gradually raised to redness. The mass is dissolved in water, and poured into a solution of sulphate of iron. A green coloured precipitate falls, which becomes prussian blue when digested in muriatic acid. The triple prussiate of potash was formerly called phlogisticated alkali. It is still useful in detecting different metals in solutions, by the colour of the precipitate which it occasions, especially iron, which it throws down of a deep blue.

SECT. II. *Of Gallic Acid.*

Gallic acid.

This acid forms one of the constituents of the substance called *nutgalls*, a concretion formed on the oak in consequence of the puncture of insects. Nutgalls come to this country chiefly from the Levant. They vary a good deal in their appearance. Scheele first separated gallic acid from nutgalls.

How obtained.

An infusion of nutgalls left to itself for some time, becomes mouldy on the surface, and lets fall small crystals. These crystals being picked out, dissolved in water, and obtained again by evaporation, constitute *gallic acid*.

The acid obtained by this process is never quite pure. If the infusion of nutgalls be evaporated to dryness, and the powdered residue be digested in pure alcohol, the alcohol, when cautiously distilled to one-eighth, leaves a residue behind it nearly colourless, which is soluble in water, and yields by evaporation gallic acid in needles, much lighter coloured and purer than that obtained by the first described process.

Its properties.

Gallic acid is white, usually with a shade of brown or yellow. It is crystallized in needles or transparent plates. Its taste is acid, and somewhat astringent; and when heated, it exhales a peculiar and rather unpleasant aromatic odour. It is soluble in 1½ parts of boiling, and in 12 parts of cold water. When the solution is heated, the acid is decomposed. When long kept, it becomes darker coloured, and the acid is likewise altered in its properties.

When heated, it sublimes, but its properties are somewhat altered. When distilled, it yields, like other vegetable acids, carbonic acid gas, and heavy inflammable air. Water is also formed, and a portion of the acid escapes, slightly modified in its nature.

It is not altered by exposure to the air. Neither oxygen gas, the simple combustibles, or incombustibles, seem to produce any effect upon it. The action of the metals is unknown.

Gallates.

The compounds of this acid, with the salifiable bases, are called *gallates*. They have scarcely been examined. When gallic acid is dropt into lime, barytes, or strontian water, it strikes a bluish red colour, and occasions a flaky precipitate. It occasions a precipitate likewise when poured into the solutions of yttria, glucina, or zirconia in acids. Upon metallic solutions it acts with considerable energy, changing their colour, and occasioning precipitates in many of them. Thus, with iron it strikes a dark blue, or almost black colour. When it precipitates metallic oxides, it seems to bring them nearer to the metallic state, and sometimes reduces them altogether. Thus gold is precipitated by it in the metallic state.

SECT. III. *Of Tannin.*

Tannin.

Nutgalls, besides gallic acid, contain several constituents; one of the most curious and important of these is tannin, which is to occupy our attention in this Section.

Tannin was first pointed out in vegetables by Deyeux, though some of its properties had been noticed long before by Lewis. Seguin first pointed out its great importance in tanning, and hence the name was given it, by which it is at present known. Proust endeavoured to obtain it in a separate state. Mr Davy added to our knowledge of its properties. But it is to Mr Hatchett that we are indebted for the most important set of new facts. He pointed out a method of making it artificially from almost all animal and vegetable substances. As Mr Hatchett's tannin differs in several respects from the tannin of nutgalls and other astringent substances, it will be proper to divide this section into two parts.

1. *Natural Tannin.*

Natural Tannin.

No unexceptionable method of obtaining tannin from nutgalls, in a state of complete purity, has yet been discovered. The best method is this:

How obtained.

Make an infusion of nutgalls in water, evaporate the infusion to dryness, pulverize the residuum, and digest the powder in repeated portions of pure alcohol till that liquid ceases to dissolve any thing. The residue is tannin tolerably pure. It may be dissolved in water, and precipitated by acetate of lead. The edulcorated precipitate being mixed with water, and a current of sulphureted hydrogen passed through it, the lead combines with sulphur and remains insoluble; while the tannin, thus set at liberty, dissolves in the water, and may be obtained by evaporating the liquid.

Its properties.

Tannin, thus obtained, is a brittle substance of a brown colour, with an astringent taste like that of nutgalls. It dissolves readily in water, and the solution, according to Trommsdorf, is not liable to become mouldy. Pure alcohol does not dissolve it; but it is soluble in alcohol diluted with a little water, as for example in alcohol of 0.818 of specific gravity, which contains $\frac{1}{10}$th of its weight of water.

It seems capable of combining with oxygen, but its properties are, by that means, completely altered; being, according to Proust, a species of *extractive*.

The action of the simple combustibles on tannin is unknown. The action of the metals is probably small, but it combines with most of the metallic oxides, and forms compounds which, for the most part, are insoluble in water. Thus it strikes a deep blue or black with solutions of iron, and if the solutions be diluted, the compound of tannin and the oxide of iron precipitates.

When a solution of *glue*, or *gelatine* as chemists term it, is poured into an aqueous solution, a precipitate immediately falls. This precipitate consists of tannin and gelatine combined together. It is insoluble in water, and composed, according to Davy, of 54 gelatine and 46 tannin. This property renders gelatine a very delicate test of tannin, which it detects when it exists, even in small proportion, in vegetable liquids.

The alkalies combine with tannin, and prevent it from precipitating gelatine, till they are saturated with an acid.

The earths combine with tannin, and form with it compounds nearly insoluble. Hence they precipitate it from the infusion of nutgalls.

Most of the acids combine with tannin, and form soluble compounds with it. Arsenic, muriatic, and sulphuric acids precipitate it from water. The sulphuric acid gradually decomposes it. Nitric acid also decomposes it, and a substance is formed having the properties of malic acid.

Such are the properties of the tannin of nutgalls, as far as they have been ascertained. The difficulty of obtaining it in a state of purity renders some of them ambiguous, and has induced chemists to employ the infusion of nutgalls in their experiments rather than tannin.

Writing ink.

This infusion is employed in considerable quantity by dyers, and it forms the principal ingredient of common *writing ink*. This liquor consists of a solution of sulphate of iron in the infusion of nutgalls. No other salt of iron tried answers so well as the sulphate. The deepest black is formed when equal weights of nutgalls and of sulphate of iron are employed. But it is not permanent unless the nutgalls amount to about thrice the weight of the sulphate. The best ink, according to Dr Lewis, who made many experiments on the subject, may be made by means of the following formula.

Logwood, ...	1 ounce.
Nutgalls, in powder,	3
Green vitriol, ...	1
Water, ...	1 or 2 quarts.

Boil the logwood and the nutgalls in water, adding new liquid in proportion to the evaporation, then strain through a cloth and dissolve the green vitriol, adding at the same time one ounce of gum arabic and a little sugar. Some recommend the addition of a little cloves to prevent the ink from moulding.

Tannin exists in many other substances besides nutgalls. The barks of many trees, the substances called catechu and kino, logwood, brazil wood, fustick, and many other vegetable bodies yield it in abundance. From the experiments of Proust, it appears that it varies in its qualities in these bodies, or that there are different species of tannin varying from each other in several respects, especially in the colour which they strike with iron. Some precipitate that metal black, some green, and some flesh-red.

2. *Artificial Tannin.*

Artificial Tannin.

The important discovery, that a substance capable of tanning leather like the tannin of nut-galls, may be formed artificially, was made by Mr Hatchett in the course of a set of experiments on the slow carbonization of vegetable bodies, and detailed by him in various papers read to the Royal Society in 1805.

How obtained.

To form it, we have only to digest diluted nitric acid on charcoal, till the whole, or nearly the whole, is dissolved, and evaporate the solution to dryness; a brown coloured matter remains, which is *artificial tannin*. 100 grains of charcoal, by this process, were converted into 120 grains of artificial tannin. A part of this increase is moisture, and it is very difficult to get red of the whole of the nitric acid, a portion of which adheres to the tannin with great obstinacy.

Its properties.

Tannin, thus prepared, is a substance of a brown colour, it has considerable lustre, and breaks with a vitreous fracture. Its taste is very bitter and highly astringent. It has no smell. It dissolves readily in cold water, forming a brown coloured solution. Alcohol, of the specific gravity 0.800, also dissolves it.

The solution is precipitated by gelatine very readily. The precipitate is brown, and composed, according to Hatchett, of 36 tannin and 64 gelatine.

Sulphuric and muriatic acids form a precipitate when poured into solutions of artificial tannin. Nitric acid does not decompose it nor alter its properties. This forms a marked distinction between natural and artificial tannin.

The alkalies unite with it, and prevent it from precipitating gelatine till they are saturated. The alkaline earths, and most of the metallic oxides, form insoluble compounds with it. Hence it precipitates most of these bodies from their solutions.

When distilled, artificial tannin yields water, a little nitric acid, and a yellow coloured liquid; on raising the fire, ammoniacal gas is disengaged with great rapidity; this is followed by carbonic acid gas, and a gas possessing the properties of azote. A bulky charcoal remains behind. From these results it is obvious that this substance consists of oxygen, azote, hydrogen, and carbon. The last constituent, no doubt, predominates.

Charcoal yields artificial tannin.

Mr Hatchett has shewn that every charcoal, both from animal and vegetable substances, provided it be in the state of charcoal, yields artificial tannin when digested with nitric acid. He has pointed out two other methods of procuring a substance possessed of similar properties. The first is by dissolving indigo and the resins, or gum resins, in nitric acid, and digesting them for a considerable time in that liquid. When the solution is evaporated to dryness, a yellow coloured matter remains, which possesses the properties of artificial tannin. The second method is by dissolving camphor and the resins in sulphuric acid, digesting till the solution becomes black, and then precipitating by pouring it into cold water. If the black powder which falls be digested in alcohol, a brown matter is taken up which possesses many of the properties of artificial tannin.

Such are the properties of the colorific acids. They act with most energy on metallic solutions, forming precipitates which vary in their colour according to the metal. It is this property which renders them of so much importance in a chemical point of view. The following Table exhibits a view of the colours which these bodies strike with the different metals, as far as is known.

Table of the colours which colorific acids strike with the metals.

Metals.	*Prussiate of Potash.*	*Gallic Acid.*	*Infusion of Nut-galls.*	*Artificial Tannin.*
Gold	Yellowish white	Reduced	Reduced	Reduced
Platinum	0	0	0	
Silver	White	Yellowish brown	Yellowish brown	Yellow
Mercury	White	Orange yellow	Orange yellow	Yellow
Palladium	Olive			
Rhodium	0

Titanium	Yellowish brown		Blood red	
Columbium	Olive		Orange	
Cerium	White	0	0	

CHAP. VII.

Of the Compounds of Chlorine.

Compounds of chlorine,

We shall in this Chapter give an account of the compounds which chlorine forms with all the other simple substances, as far as the subject has been investigated. For all the experiments hitherto made on the subject, we are indebted to Mr Davy, and his brother, Mr John Davy.

With oxygen.

1. Chlorine has the property of combining with oxygen. The compound is a gas of a yellow colour, which may be obtained by pouring diluted muriatic acid on the salt called hyperoxymuriate of potash, and applying a moderate heat. The gas may be received over mercury. It was discovered, and its properties investigated, by Mr Davy, who has given it the name of *euchloric* gas. Its colour is greenish yellow, and very intense. Water absorbs about ten

times its bulk of it. Its specific gravity is 2.61. It is composed of two parts in volume of chloric gas, and one of oxygen gas. When heated, it is decomposed, and light and heat are produced.

With hydrogen.

2. Chlorine combines very readily with hydrogen, and forms the very important compound called *muriatic acid*. When the gases, each as dry as possible, are mixed together in equal bulks, and the mixture exposed to the light of the sun, inflammation takes place, the two gases disappear, and a quantity of muriatic acid gas is formed nearly equal to them in bulk. Now, as the specific gravity of muriatic acid gas is almost exactly the mean of the specific gravity of hydrogen and chloric gas, it is inferred that it is a compound of equal bulks of these gases. Therefore muriatic acid is composed by weight of

97.24 chlorine,
2.76 hydrogen,

100.00

or of one part of hydrogen and about 35 of chlorine. But if we suppose, with Mr Davy, that the proportion of hydrogen exceeds that of chloric gas in bulk, we may consider muriatic acid as composed of one part hydrogen, and 33 of chlorine.

Muriatic acid may be obtained by putting some common salt in a small glass retort, pouring over it sulphuric acid, and receiving the product over mercury.

Muriatic acid gas is invisible, and possesses the mechanical properties of common air. Its specific gravity is 1.278, that of air being 1.000. Its smell is pungent and peculiar, and when mixed with air it forms a visible smoke, owing to its great avidity for moisture.

It does not support combustion, nor can it be breathed by animals. When a lighted taper is plunged into it, it goes out with a green coloured flame.

Water, when brought into contact with this gas, absorbs it with great rapidity, and the whole disappears. Water absorbs 515 times its bulk of this gas, and six cubic inches of water by this absorption are converted into nine. The affinity between this gas and water are very great.

Water saturated with this gas is known by the name of *liquid muriatic acid*. It has been long known, and is very much employed by chemists. When pure, it is transparent and colourless: but it very often has a greenish yellow colour, owing to the presence of iron or of some other impurity. It has the smell of muriatic acid gas, and smokes when exposed to the air. Its specific gravity is never greater than 1.203, and seldom exceeds 1.196; and when strongest, never contains more than one-fourth of its weight of acid: the rest is water.

The following Table gives us the strength and boiling point of muriatic acid of various densities. It is from the experiments of Kirwan and Dalton.

Specific gravity of acid.	Real acid per cent. by weight.	Boiling point.
1.199	25.6	
1.181	23.4	
1.166	21.6	170°
1.154	20.0	190
1.144	18.7	212
1.136	17.5	217
1.127	16.4	222
1.121	15.5	228
1.094	12.1	232
1.075	9.91	228
1.064	8.40	225
1.047	6.49	222
1.035	5.21	219
1.018	2.65	216
1.009	1.36	214

Muriatic acid combines with various bases, and forms a class of salts called *muriates*.

With carbon.

3. As far as is known at present, chlorine does not combine with carbon; but it unites with carbonic oxide, and forms an acid gas much heavier than any other gaseous body yet discovered, and called phosgen gas.

With flowers of sulphur.

4. When a current of chloric gas is made to pass over flowers of sulphur, a combination gradually takes place, the sulphur changes its colour, and a fine red liquid is formed more than twice the weight of the sulphur employed. To this compound, originally discovered by Dr Thomson, Mr Davy has given the name of *sulphurane*.

Sulphurane is a liquid of a fine red colour between scarlet and crimson. By transmitted light it appears green. Its specific gravity is 1.623. It smokes very much, is very volatile, and has a smell similar to that of sea plants. Its taste is strongly acid, hot and bitter, affecting the throat with a painful tickling. It dissolves phosphorus readily, and forms an amber coloured liquid, which at last catches fire when left to spontaneous evaporation. When dropt into nitric acid it effervesces with considerable violence. With alcohol it becomes hot, and the smell of ether becomes perceptible. When dropt into water, it is gradually decomposed. Flocks of sulphur separate, and the water contains sulphuric and muriatic acids in solution. With ammoniacal gas it forms a solid red compound, which is decomposed and converted into sulphate and muriate of ammonia and sulphur by the action of water. Such are the properties of this remarkable compound as far as they have been hitherto ascertained. We are not acquainted with the proportion of its constituents.

With phosphorus.

4. When phosphorus is introduced into chloric gas it takes fire spontaneously, and burns with a low white flame, and at the same time melts. Two substances are formed, one a clear liquid, the other a dry white matter which sublimes during the combustion. To this compound Mr Davy has given the name of *phosphorane*.

Phosphorane appears to possess some acid qualities, at least it combines with ammonia, and forms a white insoluble tasteless powder, very similar to silica in many of its properties. When phosphorane is digested in water, it is decomposed and converted into phosphoric and muriatic acids.

Boracium. 5. We are not yet acquainted with the combination of boracium and chlorine.

Potassium. 6. Chlorine readily combines with potassium, and forms the compound usually distinguished by the name of *muriate of potash.* Mr Davy proposes to give it the name of *potassane.*

Potassane. When potassium is heated in chloric gas, it burns with great splendour, and potassane is formed. The same compound is obtained when potash and chlorine are brought in contact; but in that case the oxygen gas, which previously constituted one of the ingredients of the potash, is evolved. When potash and muriatic acid are brought in contact, water is formed, and the same compound obtained.

Potassane crystallizes in irregular cubes. Its taste is salt, and rather bitter. It dissolves in thrice its weight of cold water. Little altered by exposure to the air. In a red heat it melts, and loses about three per cent. of its weight. Not sensibly soluble in alcohol.

According to the experiments of Mr Davy, it is composed of 55.5 potassium,
44.5 chlorine.

100.0

Sodium. 7. The combination of chlorine and sodium has been known and in general use from the remotest ages, under the name of *common salt* or *muriate of soda.* Mr Davy has given it the name of *sodane.*

Sodane. It exists abundantly in sea-water, from which it is obtained by evaporation. Mines of it occur also in different parts of the world. It crystallizes in cubes. Its taste is universally known, and is what strictly speaking is denominated salt. It dissolves in rather less than thrice its weight of water, and is nearly equally soluble in cold and hot water. It is insoluble in pure alcohol. It deliquesces somewhat when exposed to moist air. In a red heat it melts and loses about two per cent. of its weight. In a violent heat it evaporates.

Common salt, from the experiments of Mr Davy, is composed of 40.17 sodium,
59.83 chlorine.

100.00

Ammonia. 8. As far as we know at present, chlorine has not the property of combining with ammonia.

Barium. 9. Chlorine combines with barium, and forms the compound usually distinguished by the name of *muriate of barytes.* Mr Davy calls it *bariane.*

Bariane. This salt crystallizes in four-sided prisms, whose bases are squares; but it is obtained more commonly in tables. It has a pungent and disagreeable taste; and, like all other preparations of barytes, is poisonous. It requires rather more than twice its weight of water to dissolve it. It is not sensibly soluble in pure alcohol. It is not altered by exposure to the air. In a red heat it melts, but is not decomposed.

Strontium. 10. It combines with strontium, and forms the compound usually distinguished by the name of *muriate of strontian.* Mr Davy calls it *strontiane.*

Strontiane. This salt crystallizes in long slender hexagonal prisms, usually so minute as to have the appearance of needles. It dissolves in rather less than its weight of cold water, while boiling water dissolves any quantity of it whatever. It dissolves in about 24 parts of pure alcohol. The crystals are not much altered by exposure to the air. When heated they undergo the watery fusion, and in a red heat are converted to a white powder.

Calcium. 11. Chlorine combines likewise with calcium, and forms the substance usually distinguished by the name of muriate of lime. Mr Davy calls it *calciane.*

Calciane. This salt is not easily procured in crystals, on account of its great solubility in water. Its crystals are six-sided striated prisms, terminated by very sharp pyramids. Its taste is very bitter and pungent. At the temperature of 60° water dissolves four times its weight of this salt, and it dissolves any quantity whatever at the temperature of 100°. Alcohol seems capable of dissolving more than its own weight of this salt. This salt deliquesces very speedily when exposed to the atmosphere. When heated, it melts and loses its water of crystallization. In a violent heat it loses also a portion of its acid, and then has the property of shining in the dark. In that state, it is called the *phosphorus of Homberg.*

Magnium. 12. Magnium, as far as we know at present, does not combine with chlorine.

Mr Davy considers bariane, strontiane, and calciane, as composed of 32.9 of chlorine, combined with 71 barium, 46 strontium, and 21 calcium.

Gold. 13. The compound of gold and chlorine, usually called *muriate of gold,* has not been accurately examined. It is a yellow coloured salt, having an acrid taste, and deliquescing in the air.

Platinum. 14. Neither are we well acquainted with *muriate of platinum,* which is in reality a compound of chlorine and platinum.

Silver. 15. Silver combines with chloric acid in the proportion of 2 grains of the metal to $\frac{9}{10}$ths of a cubic inch of the gas. The compound is an insoluble powder, usually called *hornsilver*, or *muriate of silver.* Mr Davy calls it *argentane.*

Argentane. This salt is easily obtained, by pouring common salt into a solution of nitrate of silver. It is at first a heavy white curdy precipitate, but it soon blackens when exposed to the air. It is insoluble in water. When heated to about 500°, it melts into a grey coloured semi-transparent mass, having some resemblance to horn, and formerly called *luna cornea.* When heated with potash, or when boiled with water and iron filings, it is decomposed, and the silver reduced to the metallic state. It dissolves in ammonia; it is likewise soluble in muriatic acid, and by that means may be obtained in octahedral crystals. One hundred parts of dry muriate of silver contain about 75.5 parts of pure silver.

Argentane is composed of
75.5 silver,
24.5 chlorine,

100.0

Mercury. 16. Chlorine combines in two proportions with mercury, and forms two compounds of great importance, distinguished by the names of *corrosive sublimate* and *calomel.* The first is a compound of two grains of mercury, and 1.05 cubic inches of chloric gas: the second contains the same quantity of mercury united to half the portion of gas.

Corrosive sublimate was known to the alchymists. A vast number of methods of preparing it have been made public. The most common method is to mix together equal weights of dry oxynitrate of mercury, decrepitated common salt, and calcined sulphate of iron. One-third of a matrass or phial is filled with this mixture. The vessel is placed in a sand bath, and gradually heated to redness. A cake of corrosive sublimate sublimes into the upper part of the vessel. It may be formed directly by dissolving red oxide of mercury in muriatic acid.

It has usually the form of a white semi-transparent cake composed of small prisms. Its specific gravity is 5.1398. Its taste is excessively acrid and caustic, and it leaves for a long time a very disagreeable styptic metallic impression on the tongue. It is one of the most virulent poisons known. It is soluble in about 20 parts cold and 3 parts boiling water. Alcohol dissolves nearly half its weight of it. It is not altered by exposure to the air. When heated it sublimes very readily, and the fumes are very dangerous when inhaled. It is soluble in sulphuric, nitric, and muriatic acids, decomposed by the alkalies, and precipitated of a brick red colour. The alkaline earths likewise decompose it, and ammonia forms with it a triple compound.

Calomel is prepared by triturating four parts of corrosive sublimate and three parts of mercury in a mortar, and then subliming the mixture in a matrass. It is a dull white mass, which becomes yellowish when reduced to powder. When slowly sublimed, it crystallizes in four-sided prisms, terminated by pyramids. Its specific gravity is 7.1758. It is insoluble in water. It is tasteless. When rubbed in the dark it phosphoresces. It requires a higher temperature to sublime it than oxymuriate of mercury. Chlorine and nitric acid convert it into oxymuriate corrosive sublimate.

Copper. 17. Chlorine combines in two proportions with copper, and forms two compounds, distinguished by the names of *cuprane* and *cupranea*. To form the first of these compounds, two grains of copper combine with 3.4 cubic inches of chloric gas.

Cuprane. Cuprane was discovered by Boyle, who gave it the name of *resin of copper*, from its colour. Proust afterwards discovered it anew, and gave it the name of *white muriate of copper*. It may be obtained by exposing copper filings to the action of chloric gas, by heating together two parts of corrosive sublimate, and one part of copper filings, by boiling copper filings in muriatic acid, or by exposing copper filings, partially immersed in muriatic acid, to the atmosphere. Cuprane is fusible in a heat just below redness; and in a close vessel it is not decomposed nor sublimed by a strong red heat; but when the air is admitted, it is dissipated in dense white fumes. It is insoluble in water, effervesces in nitric acid, is soluble in muriates, but is precipitated unaltered by the effusion of water. It is usually opake, of a dark brown colour, and of a confused hackly texture; but by slow cooling, it may be obtained light yellow, semitransparent, and crystallized in small plates.

Cupranea. Cupranea may be formed by heating cuprane in chloric gas; but it is most readily obtained by evaporating the deliquescent muriate of copper to dryness, at a temperature not much above 400° Fahrenheit. It is a yellow powder, decomposed by heat; absorbs water from the atmosphere, and is changed into deliquescent muriate. The constituents of these two compounds, according to the experiments of Mr John Davy, are as follows:

Cuprane of 60 copper + 32.77 chlorine = 92.77
Cupranea of 60 + 67.20 = 127.20

Iron. 18. Iron likewise combines in two proportions with chlorine, forming two compounds, which have received the names of *ferrane* and *ferranea*.

Ferrane. Ferrane may be obtained by evaporating the green muriate of iron to dryness, and exposing the residue to a red heat in a glass tube, with a very narrow orifice. It has a greyish variegated colour, a metallic splendor, and a lamellar texture. It dissolves in water, and forms the green muriate of iron.

Ferranea. Ferranea may be obtained by burning iron wire in chloric gas. It sublimes during the combustion in the form of small brilliant iridescent plates. It dissolves in water, and the solution is identical with the red muriate of iron.

These two compounds, according to the experiments of Mr John Davy, are composed as follows:

Ferrane of 29.5 iron + 33.60 chlorine = 63.1
Ferranea of 29.5 + 55.50 = 85.0

Tin. 19. Tin likewise combines with two doses of chlorine, and forms the two compounds distinguished by the names of *stannane* and *stannanea*.

Stannane. Stannane may be obtained by heating together an amalgam of tin and calomel, or by evaporating the muriate of tin to dryness, and fusing the residue in a close vessel. It has a grey colour, a resinous lustre and fracture, and takes fire when heated in chloric gas. It melts at a heat below that of dull redness; when exposed to a strong heat, it is partially decomposed. It is converted into stannanea when heated with corrosive sublimate, nitre, red oxide of mercury, and hyperoxymuriate of potash.

Stannanea. Stannanea, or liquor of Libavius, may be obtained by heating together amalgam of tin and corrosive sublimate, or by mixing a concentrated solution of peroxide of tin in muriatic acid with sulphuric acid, and applying a moderate heat. This liquor smokes violently when exposed to the air. When mixed with about one-third of its weight of water, it crystallizes. Mr John Davy found, that it had the property of setting oil of turpentine on fire. According to the experiments of this gentleman, these two compounds are composed as follows:

Stannane of 55 tin + 33.4 chlorine = 88.4
Stannanea of 55 + 67.0 = 122.0

Lead. 20. Lead, as far as is known, combines only in one proportion with chlorine. Plumbane. *Plumbane* may be obtained by decomposing the nitrate of lead by means of muriatic acid, and fusing the precipitate in a glass tube with a narrow orifice. It is the substance formerly well known under the name of horn lead. It is composed of 97.2 lead + 33.8 chlorine.

Zinc. 21. Zinc only forms one compound with chlorine. Zincane. It has received the name of *zincane*. It may be obtained by evaporating to dryness the muriate of zinc, and fusing the residue in a glass tube. It is not volatile at a strong red heat in close vessels. When exposed to the air it diliquesces. It is composed of 34.5 zinc + 34.4 chlorine.

Bismuth.

22. Bismuth combines readily with chlorine, and forms the substance formerly known by the name of *butter of bismuth.* It is now called *bismuthane,* and is composed of 67.5 bismuth + 34 20 chlorine.

Bismuthane.

Antimony.

23. Two grains of antimony absorb 3.1 cubic inches of chloric gas. The result is the compound formerly called *butter of antimony.* It was prepared by triturating together one part of antimony and two parts of corrosive sublimate, and distilling the mixture. The butter of antimony passes over in the state of a thick fatty mass of a greyish white colour, and often crystallized in four-sided prisms. It is very caustic, becomes coloured when exposed to the air, and melts at a moderate temperature. Antimonane (as this compound is called) is composed of 42.5 antimony + 34.6 chlorine.

Antimonane.

Tellurium.

24. Two grains of tellurium absorb 2.4 cubic inches of chloric gas. The product is a substance resembling butter of antimony in its appearance.

Arsenic.

25. Two grains of arsenic absorb 3.6 cubical inches of chloric gas. The product is the substance usually called *butter of arsenic.* A dense, limpid, highly volatile fluid, a non-conductor of electricity, and of high specific gravity. When decomposed by water, it gives muriatic acid, and white oxide of arsenic, similar, in this respect, to most of the combinations of chlorine with the metals. It is composed of 21.9 arsenic + 33.6 chlorine.

Manganese.

26. Manganese absorbs chloric gas, and forms a compound of a deep brown colour, and not volatilized at a dull red heat. It may be obtained by heating the dry muriate of manganese to redness. It is pink coloured, and composed of 28.4 manganese, + 33.6 chlorine.

Tungsten.

27. Tungsten absorbs chloric gas, and forms an orange-coloured sublimate.

The remaining combinations of chlorine with metals are still unknown.

Chap. VIII.

Of Compound Combustibles.

Compound combustibles.

The compound combustibles are usually composed of carbon and hydrogen, or of carbon, hydrogen, and oxygen. They are very numerous, including almost all the animal and vegetable bodies. But the progress of the investigation of these bodies, and their importance in chemical investigations, is not such as to warrant their introduction here. We shall describe only those compound combustibles which are of importance as instruments of chemical analysis. These may be comprehended under the five following heads. 1. Alcohol. 2. Ethers. 3. Volatile oils. 4. Fixed oils. 5. Bitumens.

Sect. I. *Of Alcohol.*

Alcohol.

The liquid called *alcohol,* or *spirit of wine,* is obtained when wine, beer, or other fermented liquors are subjected to distillation. The ancients were unacquainted with it. We do not know the discoverer of this liquid, but it was known to the alchymists, and introduced by them into pharmaceutical preparations.

How obtained.

It is by the distillation of fermented liquors that ardent spirits are obtained, and they receive various names according to the nature of the substance employed. Thus *brandy* is obtained from *wine, rum* from the fermented juice of the *sugar cane, whisky* and *gin* from the fermented infusion of *malt* or *grain.* Now, ardent spirits consist almost entirely of three ingredients; namely, water, pure spirit or alcohol, and a little oil or resin, to which they owe their flavour and colour. When these liquids are re-distilled, the first portion that comes over is a fine light transparent liquid, known in commerce by the name of *rectified spirits.* When as highly rectified as possible, the specific gravity of the liquid obtained does not appear to be less than 0.820, and is generally more. Alcohol, by this process, cannot be deprived of the whole of the water with which it is combined. The best method of getting rid of the water is to expose a quantity of the salt called *muriate of lime* to a red heat, to put it into a retort while still warm, and to pour over it a portion of alcohol of about 0.820, nearly equal to it in weight. The alcohol dissolves the salt, and much heat is evolved. This mixture is to be exposed to heat, and the alcohol distilled off. The salt retains the water, and the alcohol comes over of the specific gravity 0.791 at 68°, or 0.796 at 60°. In this state it is the strongest alcohol that can be procured. It is, therefore, called *pure,* or *absolute alcohol.* The alcohol of commerce is never so strong as this; its specific gravity is seldom under 0.837.

Its properties.

Alcohol, thus procured, is a transparent liquid, colourless as water, of a pleasant smell, and a strong penetrating agreeable taste. When swallowed, it produces intoxication. It cannot be frozen in the greatest degree of cold to which it has been exposed, and it has been cooled down in thermometer tubes to —91°. It is very volatile, evaporating spontaneously at the common temperature of the atmosphere. When heated to 173½° it boils, and is converted into an elastic fluid, possessing the mechanical properties of air, but more than twice as heavy.

It combines with water in every proportion, and forms spirits of different degrees of strength according to the quantity of water present. The common spirits of commerce are nothing else than such combinations of alcohol and water. The proportion of alcohol present in these liquids is best judged of by their specific gravity. The specific gravity of pure alcohol is 0.796. That of water 1.000. Hence the lighter a spirit is, the stronger is it. Alcohol of 0.820 contains nearly $\frac{1}{10}$th of its weight of water; alcohol of 0.840 contains $\frac{17}{100}$ parts of water. What in this country is called *proof spirits,* is of the specific gravity 0.920. It was understood to be a mixture of equal bulks of alcohol and water. This, however, is not the case. It contains 0.52 of its weight of water. When spirits are weaker than 0.920, they are said to be *under proof;* when stronger, to be *above proof.* The spirits retailed in Scotland are almost always under proof, and sometimes indeed very weak.

Neither common air nor oxygen gas act upon alcohol at the common temperature, but in high temperatures the case is different. When alcohol is kindled in the open air, it burns all away without leaving any residuum. The flame is blue, and if the vapours emitted be collected, they are found to consist of carbonic acid and water, and the portion of water formed is greater than the whole of the alcohol consumed. When the vapour of alcohol is mixed with oxygen gas, it may be kindled by an electric spark provided the temperature be above 70°, a detonation takes place, the alcohol is consumed, and water and carbonic acid formed. When alcohol is passed, in the state of vapour, through a red-hot porcelain or metallic tube, it is decomposed, and a variety of new products evolved. These are, 1. A great quantity of inflammable air, which, according to Saussure junior, consists of oxygen, hydrogen, carbon, and azote; 2. A little charcoal; 3. A little oil, partly in crystals, partly fluid; 4. A portion of water, holding in solution traces of acetic acid and ammonia; 5. A little of an acid which resembles the benzoic. By estimating the proportions of ingredients formed in these decompositions, chemists have endeavoured to ascertain the constituents of alcohol. The following is the result obtained by Saussure junior, who has lately published an elaborate set of experiments on the constituents of alcohol. It is composed of

Composition.

Oxygen, - - -	37.85
Carbon, - - -	43.65
Hydrogen, - - -	14.94
Azote, - - - -	3.52
Ashes, - - - -	0.04
	100.00

Alcohol has little action on the simple combustibles. On hydrogen and charcoal it seems to produce no effect. But it dissolves a little phosphorus and sulphur. If phosphureted alcohol be dropt into water, a lambent flame is observed playing on the surface of the liquid, and the phosphorus is disengaged.

Alcohol dissolves the fixed alkalies. It is by means of it, indeed, that these bodies are obtained in a state of purity. The earths are scarcely acted on by alcohol. It absorbs a quantity of nitrous gas, which cannot afterwards be expelled by heat.

The strong acids decompose alcohol. The rest combine with it, and form a set of compounds hitherto but little examined. It dissolves also a considerable number of salts, especially the acetates, muriates and nitrates. The sulphates are all insoluble in it. The colour of the flame of alcohol is tinged by various bodies. Thus nitrate of strontian tinges it purple; boracic acid and the cupreous salts tinge it green; muriate of lime gives it a light red colour; nitre and oxymuriate of mercury a yellow colour.

SECT. II. *Of Ethers.*

Ethers.

When alcohol is acted upon by several of the acids, a fragrant liquid is formed, to which the name of *ether* has been given. These ethers are named from the acid employed in forming them. As they differ in their properties, it will be requisite to describe them separately.

1. *Sulphuric Ether.*

Sulphuric ether.

This liquid was known about the end of the 15th century, and some of its properties were described by Boyle; but the attention of chemists was first drawn to it by a paper published in the Philosophical Transactions for 1730, by a German who called himself Dr Frobenius.

How obtained.

It may be obtained by distilling a mixture of equal parts of alcohol and sulphuric acid in a glass retort, to which a large receiver is attached. The ether condenses in the receiver. When first prepared, it contains some sulphurous acid, which is removed by putting some powdered chalk into it, and agitating repeatedly in a close phial, till the sulphurous acid smell is dissipated. The ether is then distilled a second time. It still retains a portion of alcohol, from which it may be freed by adding to it dry muriate of lime as long as it will dissolve that dry salt, and leaving the solution in a well corked phial. The muriate of lime dissolved in the alcohol gradually subsides, and the pure ether floats on the top. It may be decanted off.

Its properties.

Ether thus obtained is a limpid and colourless fluid like water. It has a peculiar and agreeable smell, and a hot pungent taste. Its specific gravity when pure is only 0.632 at 60°; but the ether of commerce is seldom lower than 0.775, owing to the alcohol which it contains.

It is so volatile that it cannot be poured from one vessel to another without considerable loss. When exposed to the open air, it disappears in a very short time. It boils at 98°, and in a vacuum at —20°. When evaporated, it produces a considerable degree of cold, so that water may be easily frozen by means of it even in summer. The specific gravity of the vapour of ether, according to Dalton, is 2.25, that of air being 1.00. When ether is exposed to a cold of —46°, it freezes and crystallizes.

Neither oxygen gas nor air produce any effect upon ether at the common temperature of the atmosphere; but when kindled in contact with these fluids, it burns with a strong white flame, giving out a great deal of light and heat. The products in this case are carbonic acid and water. It consumes, during its combustion, about seven times its bulk of oxygen, supposing the ether in the gaseous state. When mixed with oxygen gas in that proportion, it explodes very loudly when an electric spark is passed through the mixture. Various attempts have been made to estimate the constituents of ether by consuming it with oxygen gas, and ascertaining the products obtained. The following is the composition of ether, according to the experiments of Saussure junior.

Composition.

Carbon, - - -	58.20
Hydrogen, - - -	22.14
Oxygen, - - -	19.66
	100.000

These numbers indicate a much greater proportion of carbon and hydrogen, and a much smaller proportion of oxygen in sulphuric ether than in alcohol.

When ether is passed through a red hot porcelain tube, it is decomposed and converted into oil, charcoal, water, and a great proportion of heavy inflammable gas.

Ether combines only in a small proportion with water. Ten parts of that liquid dissolve about one part of ether. But alcohol unites with ether in any proportion.

Ether dissolves a little phosphorus and sulphur, but does not seem to act upon the other simple combustibles. It has no action on the metals, but revives those metallic oxides which readily part with their oxygen, as the oxides of gold and silver. It dissolves the muriate of gold, and the oxymuriate of mercury.

It does not appear to have any action on the alkalies or earths. It readily dissolves ammonia and nitrous gas.

Sulphuric acid seems capable of converting it into sweet oil of wine. Oxymuriatic acid sets it on fire spontaneously. The action of the other acids has not been ascertained.

It dissolves the fixed and volatile oils, and bitumens, but does not act upon gums.

From its constituents, as ascertained by Saussure, compared with those of alcohol, it is obvious that, during the formation of sulphuric ether, the alcohol is decomposed. This decomposition, according to Fourcroy and Vauquelin, is owing to the high temperature to which the alcohol is subjected, in consequence of being prevented from evaporating so easily by the sulphuric acid with which it is combined.

2. *Nitric Ether.*

Nitric Ether.

This ether is mentioned by some of the older chemists, but its properties were almost unknown till it was lately examined by Thenard.

How obtained.

It may be formed by distilling a mixture of equal parts of alcohol and nitric acid of the specific gravity 1.283 in a retort, from which passes a tube that goes to the bottom of a tall glass jar half filled with a saturated solution of common salt in water. Several of these jars are connected together by tubes, and from the last a tube passes to convey the gaseous products to the water trough. The ether condenses on the surface of the liquid in these jars. It contains at first a little nitrous and acetic acids, from which it is purified by agitation with chalk in a close phial till it ceases to redden vegetable blues.

Its properties.

Nitric ether thus prepared has a pale yellow colour, and a very strong ethereal odour. Its taste is strong and quite peculiar. It is rather heavier than alcohol, but much more volatile than sulphuric ether. Hence it only moistens bodies for a moment, and produces a considerable cold by its evaporation. The heat of the hand is sufficient to make it boil.

It dissolves in 48 parts of water, and communicates to that liquid an odour like that of apples. It dissolves in alcohol in any proportion. It burns with a white flame, and as brilliantly as sulphuric ether. When kept for some time, both nitric and acetic acids are evolved in it. The same acids make their appearance if the ether be heated, or if it be agitated in water. When brought in contact with a little of these acids, it instantly absorbs them, and acquires the property of reddening vegetable blues.

At the temperature of 70°, it quintuples the bulk of gases. At that temperature its vapour is capable of supporting a column of mercury 28.74 inches high. Hence its boiling point is obviously only a degree or two above 70°.

Composition.

From the analysis of Thenard, the constituents of nitric ether are as follows:

Oxygen, - - -	48.52
Carbon, - - -	28.45
Azote, - - -	14.49
Hydrogen, - - -	8.54
	100.00

It is probable that it contains nitric acid ready formed, as one of its constituents, and that this acid is neutralized by the spirit, and thus prevented from acting on vegetable blues. It is obvious from the preceding account of its properties, that nitric ether differs entirely from sulphuric ether in its nature.

3. *Muriatic Ether.*

Muriatic ether.

After the discovery of sulphuric and nitric ether, various attempts were made to procure muriatic ether, and different processes were suggested. Sometimes a mixture of alcohol and those metallic muriates that contain an excess of acid were distilled, and sometimes alcohol was saturated with muriatic acid gas and distilled. The nature of muriatic ether was almost unknown till a set of experiments was made on it by Gehlen in 1804. Thenard made another in 1807. To the labours of these two chemists we are indebted for all the knowledge we possess of this singular fluid.

How obtained.

It may be obtained by distilling in a retort equal bulks of alcohol and muriatic acid, both as strong as possible. From the retort a tube passes into a Woulfe's bottle, partly filled with water, and from the bottle another tube passes into the water trough. The whole of the ether formed assumes the gaseous form if the temperature be as high as 70°, and may be collected in jars over water. A mixture of acid and alcohol weighing 30 ounces troy, yields more than 1200 cubic inches of this ethereal gas.

Its properties.

This gas is colourless; it has a strong ethereal smell, and a sweetish taste. It produces no change on vegetable blues or lime water. Its specific gravity is 2.219, that of air being 1.000. At the temperature of 64° water absorbs its own bulk of this gas.

At the temperature of 52° it loses its gaseous form, and becomes liquid ether. It may be obtained in that state by passing it into a jar surrounded with ice. In its liquid state it is colourless like water, and has the same smell and taste as when gaseous. At the temperature of 41° its specific gravity is 0.874. It has no effect on vegetable blues. It is much more volatile than sulphuric or even nitric ether, assuming the gaseous form when not hotter than 64°. It burns with a green coloured flame, and a great quantity of muriatic acid is disengaged during the combustion. Thus it appears that muriatic acid is one of its constituents. But as the presence of that acid cannot be detected before combustion by the usual tests, it is obviously neutralized by the other constituents of the ether. Thenard has endeavoured to ascertain the constituents of this ether. The following are the proportions which he found:

Composition.

Muriatic acid,	29.44
Carbon,	36.61
Oxygen,	23.31
Hydrogen,	10.64
	100.00

During the formation of muriatic ether, no gas whatever is evolved except the ether, and no new product appears except the ether itself. A portion of the muriatic acid disappears, and exactly the same portion makes its appearance again when the ether is burnt. These effects render it probable that muriatic ether is a combination of muriatic acid and alcohol. But if any dependence can be put in the above analysis, and in Saussure's analysis of alcohol, it is obvious that the alcohol in entering into the composition of muriatic ether has been altered, as its constituents are not in the same proportion as in pure alcohol.

4. *Acetic Ether.*

Acetic ether.

Acetic ether was discovered in 1759 by the Count de Lauraguais, who obtained it by distilling a mixture of alcohol and acetic acid. The process has been often repeated, and has been improved since its original discovery. Thenard has lately examined the properties of this ether.

How obtained.

He obtained it by distilling a mixture of strong acetic acid and alcohol in a retort, and repeating the distillation twelve times. No gas was found, nor any symptom of the decomposition of either of the substances used exhibited. He then saturated the acid with potash, and by distilling the liquid off acetate of potash, he got the ether in a separate state.

Its properties.

Acetic ether is limpid and colourless. It has an agreeable odour of ether and acetic acid. It has a peculiar taste, bearing no resemblance to that of alcohol. It does not redden vegetable blues. At the temperature of 44½°, its specific gravity is 0.866. It boils at the temperature of 160°. It burns with a yellowish white flame, and acetic acid is developed. It undergoes no change by keeping. At the temperature of 62°, it requires more than seven times its weight of water to dissolve it. It seems, from the preceding account, to be a kind of combination of acetic acid and alcohol, substances which it seems have the property of neutralizing each other.

5. *Phosphoric Ether.*

Phosphoric ether.

From the late experiments of Boullay, it appears that ether may be formed also by means of phosphoric acid. This acid, of the consistence of honey, was put into a retort, and heated nearly to the temperature of boiling water. Alcohol was then introduced by means of a funnel passing to the bottom of the acid, and the mixture distilled. A liquid was obtained, which, when rectified off muriate of lime, yielded an ether possessing all the properties of sulphuric ether.

How obtained.

Besides these ethers, several others have been formed by means of other acids. Indeed, from the late experiments of Thenard, there is reason to believe that almost all the remaining acids may be made to combine with alcohol, and to form a liquid which might be denominated an ether, by distilling a mixture of alcohol, sulphuric acid, and the acid in question.

From the preceding detail, it appears that there are two kinds of ether essentially distinct: The first, consisting of sulphuric and phosphoric ethers, is formed by the decomposition of alcohol, and contains no acid. All the others contain an acid, and several of them seem to be combinations of an acid and alcohol. Alcohol appears to have the property of neutralizing acids, a property not suspected till lately; though several other vegetable substances seem to possess the same property.

SECT. III. *Volatile Oils.*

Volatile oils.

The term *oil* is applied to a number of liquids, which, when dropt upon paper, sink into it, and make it semitransparent, or give it what is called a *greasy* stain. Chemists have divided them into two classes, *fixed* and *volatile.*

Their properties.

Volatile oils, called also *essential oils*, are distinguished by the following properties:

1. Liquid, often as liquid as water; sometimes viscid.
2. Very combustible.
3. An acrid taste and a strong fragrant odour.
4. Volatilized at a temperature not higher than 212°.
5. Soluble in alcohol, and imperfectly in water.
6. Evaporate without leaving any stain on paper.

How obtained.

Volatile oils are almost all obtained from vegetables, and they exist in every part of plants except the cotyledons of the seed, where they have never been found. They are sometimes obtained from plants by simple expression. But in general they are procured by mixing the vegetable substance containing them with water, and distilling. The oil comes over along with the water, and swims on its surface in the receiver.

They are very numerous, but a detailed account of each would not be interesting; a general account of their properties will be sufficient for our purpose.

Most of them are liquid. Some indeed are as liquid as water, as oil of turpentine. Some are viscid, and some of the consistence of butter, or even more solid.

Their colours are very various. Some are colourless like water. Some yellow, brown, blue, green, &c.

Their odours are so various as to defy all description. It is sufficient to say, that all the fragrance of the vegetable kingdom resides in volatile oils. Their taste is acrid, and sometimes they are even corrosive.

Their specific gravity is also various. Oil of turpentine, the lightest oil known, is 0.792, and oil of sassafras, the heaviest, is 1.094.

They evaporate very readily in the open air, diffusing their fragrant odour around. In close vessels the heat necessary to distil them over appears to be greater. When cooled they congeal; but the temperature necessary to produce this effect varies in different oils. Some become solid at 50°, others not till cooled down to —17°. Several of them yield crystals of camphor and of benzoic acid when thus treated.

When exposed to the light, they acquire consistency, and assume a brown colour. Dr Priestley ascertained, that they imbibe oxygen with avidity. Probably these changes are connected with that absorption. By long exposure, several of them assume the form of resins.

When heated sufficiently, they take fire, and burn with a strong yellow flame, emitting a great quantity of smoke. The products of the combustion, besides the soot deposited, are water and carbonic acid.

When agitated in water, they render it milky, and communicate their peculiar odour. They dissolve in alcohol, ether and fixed oils.

They dissolve a little phosphorus and sulphur, but do not act on hydrogen or charcoal.

The alkalies and earths act but feebly on the volatile oils. The compounds formed have been called *saponules*. It is probable that they assume the form of resins before they combine with these bodies.

Sulphuric acid decomposes them, converting them first into a kind of resin, and at last into charcoal. Concentrated nitric acid sets them on fire. The diluted acid converts them into a kind of yellow resin.

They scarcely act upon metals; but they have a tendency to reduce some of the metallic oxides.

From the products obtained when the volatile oils are burnt, it has been concluded that they are compounds of carbon and hydrogen. But no exact analysis of any of them has hitherto been made.

Sect. IV. *Of Fixed Oils.*

Fixed oils.

The fixed oils, which are of so extensive utility, have been known from the remotest ages. They may be distinguished by the following properties.

Their properties.

1. Liquid, or easily become so when exposed to a gentle heat.
2. An unctuous feel.
3. Very combustible.
4. A mild taste.
5. Boiling point not under 600°.
6. Insoluble in water and alcohol.
7. Leave a greasy stain upon paper.

How obtained.

These oils, called also *fat*, or *expressed oils*, are obtained partly from animals, partly from vegetables, by simple expression. They occur chiefly in the seeds of bicotyledinous plants, and in the livers of animals. Whale oil, spermaceti oil, olive oil, and linseed oil, may be mentioned as examples of fixed oils.

Fixed oil is usually liquid, with a certain degree of viscidity. It has usually a yellowish or greenish tinge. Its taste is sweet, or nearly insipid. When fresh it has no smell.

Many solid bodies also are obtained from vegetables which have been hitherto confounded with the fixed oils, as palm oil, shea butter, &c. From the late experiments of Dr Bostock, these substances seem to approach the nature of wax rather more than that of fixed oils.

The fixed oils are all lighter than water. Their specific gravity varies from 0.968 to 0.892.

Fixed oil does not begin to evaporate till heated above 212°. As the heat increases, a pretty copious vapour may be seen to rise; but the oil does not begin to boil till heated nearly to 600°. It may be distilled over, but it is always altered by the process. Some water and acetic acid seem to be formed; heavy inflammable air is given out. The oil deepens in colour, and acquires a disagreeable taste and smell.

Fixed oil, when kindled, burns with a yellowish white flame, and is decomposed. The products are carbonic acid and water. When exposed to cold, they congeal or crystallize, and at the same time their bulk diminishes very considerably.

When exposed to the action of air, they undergo different changes according to the nature of the oil. They gradually absorb oxygen and become solid. Now there are some that retain their *transparency* after they have become solid, while others assume the appearance of *tallow* or *wax*. Those that remain transparent are called *drying oils*; those that become opake, are called *fat oils*.

Drying oils.

The drying oils are used as a vehicle of paints and varnishes. Linseed, nut, poppy, and hempseed oils belong to this class. They acquire the property of drying oils more completely after they have been boiled. For some purposes it is common to set them on fire, and, after they have burnt for some time, to extinguish them, and continue the boiling till they have acquired the requisite viscidity. By this process, they lose the property of leaving a greasy stain upon paper, and acquire many properties in common with the resins. In this way, nut-oil and linseed-oil are prepared for printers ink. The oil, thus altered, still continues insoluble in water and alcohol, but it readily unites with fixed oil.

Fat oils.

The *fat oils*, when exposed to the air, gradually become thick, opake, and white, and assume an appearance very much resembling wax or tallow. Olive-oil, oil of sweet almonds, of rape-seed, and of ben, may be mentioned as examples of this class.

The action of the simple combustibles on the fixed oils is not very remarkable. Hydrogen has no action. Charcoal renders them purer when they are filtered through it; but separates from them with such difficulty that it cannot be employed for that purpose with advantage.

They dissolve a little phosphorus and sulphur when assisted by heat.

They are insoluble in water, alcohol, and ether; but they unite readily with each other, with volatile oils, with bitumens, and with resins.

The fixed alkalies combine with them readily, and form with them the important compound called *soap*. Potash forms with them only soft soap, while soda forms hard soap. The earths likewise and metallic oxides combine with the fixed oils, and form a kind of soap insoluble in water.

Sulphuric acid gradually decomposes the fixed oils, blackening their colour, and at last evolving charcoal. Nitric acid acts with still greater energy. When poured suddenly on the drying oils, it sets them on fire. When suddenly diluted, it converts them all into substances similar to resins or tallow.

The fixed oils oxidize some of the metals, as copper and mercury. They combine with various metallic oxides, as those of arsenic, lead, and bismuth; and are capable of forming with several, the viscid compounds called *plasters*.

They are liable, by keeping, to become *rancid*. They become thick, acquire a brown colour, an acrid taste, and a disagreeable smell. The oil, thus altered, converts vegetable blues to red, and of course contains an acid. This change is, at present, ascribed to a decomposition of the mucilaginous matter which is dissolved in all oils, or to the action of that matter in the oil.

When oils are burnt, the only products are carbonic acid and water. Lavoisier, from a set of experiments made in this way on olive-oil, deduced its composition as follows:

Carbon,	79
Hydrogen,	21
	100

But the experiments of Thenard and Gay-Lussac, made in a different way, give its constituents as follows:

Carbon,	77.213
Hydrogen,	13.360
Oxygen,	9.427
	100

Many oils occur in the vegetable kingdom, which are intermediate in their properties between the fixed and volatile oils. Like the volatile oils, they are soluble in alcohol; but, like the fixed, they cannot be distilled over with that liquid. Hence they may be obtained by digesting the substance containing them in alcohol, and then separating the alcohol by evaporation.

Empyreumatic oils.

Many oils are formed when animal and vegetable bodies are exposed to a heat above that of boiling water. These oils are called *empyreumatic*. They are usually dark-coloured, have an acrid taste and a disagreeable smell, and possess most of the properties of the volatile oils.

SECT. V. *Of Bitumens.*

Bitumens.

The term *bitumen* has been often applied to all the inflammable substances which occur in the earth. But it is better to limit it to those *fossil bodies* only which have a certain resemblance to oily and resinous substances. They may be divided into two classes. The first set possess nearly the properties of volatile oils; while the second set possess a peculiar character. The first class may be called *bituminous oils*. The second, *bitumens proper*.

1. *Bituminous Oils.*

Bituminous oils.

Only two species of bituminous oils have been hitherto examined, namely, *naphtha* or *petroleum*, and *maltha* or *sea wax*.

Naphtha.

1. Naphtha, or petroleum, is an oil of a brownish yellow colour. When pure, fluid as water, and pretty volatile. Its specific gravity varies from 0.730 to 0.878. It has a peculiar smell. When heated, it may be distilled over without alteration. It unites with alcohol, ether, volatile and fixed oils, and, as far as is known, possesess all the characters of volatile oils.

When found in the earth pure, it is distinguished by the name of *naphtha*; when less fluid and darker coloured, it is called *petroleum*. When petroleum is distilled, naphtha is obtained from it.

Maltha.

2. Maltha, or sea-wax, is a solid substance found on the Baikal lake in Siberia. It is white, melts when heated, and on cooling assumes the consistence of white cerate. It dissolves in alcohol, and seems to possess the character of a solid volatile oil.

2. *Proper Bitumens.*

Proper bitumens.

The true bituminous substances may be distinguished by the following properties:

1. They are either solid, or of the consistence of tar.
2. Their colour is usually brown or black.
3. They have a peculiar smell, or at least acquire it when rubbed. This smell is known by the name of the *bituminous odour*.
4. They become electric by friction, though not insulated.
5. They melt when heated, and burn with a strong smell, a bright flame, and much smoke.
6. They are insoluble in water and alcohol, but dissolve most commonly in ether and in fixed and volatile oils.
7. They do not dissolve in alkaline leys, nor form soap.
8. Acids have little action on them; the sulphuric scarcely any: the nitric, by long and repeated digestion, dissolves them, and converts them into a yellow coloured substance, soluble both in water and alcohol.

The pure bitumens at present known are three, namely, *asphaltum*, *mineral tar*, and *mineral caoutchouc*. United to resin, it forms a curious substance called *retinasphaltum*. United to charcoal, it forms the various species of pit-coal so important as articles of fuel.

Asphaltum.

1. Asphaltum. This substance occurs in great abundance in the island of Trinidad, on the shores of the Dead Sea, in Albania, and in other places. Its colour is black, with a shade of brown, red, or grey. It is heavier than water. It is insoluble in acids, alkalies, water, and alcohol; but soluble in oils, petroleum, and sulphuric ether. See ASPHALTUM.

Mineral tar.

2. Mineral tar. This substance is found in Barbadoes and other places. It is named from its consistence and appearance. It seems to be a mixture of petroleum and asphaltum. Accordingly, when distilled, abundance of petroleum is obtained, of a brown colour, but very fluid.

Mineral caoutchouc.

3. Mineral caoutchouc is a singular substance, hitherto found only in Derbyshire. It is soft and elastic, not unlike common caoutchouc or Indian rubber. Its colour is dark brown, with a shade of green or red. It resists the action of almost all liquid menstrua. Neither alcohol, alkalies, nor nitric acid, affect it. Even oils and petroleum are incapable of dissolving it. When heated it melts, and con-

tinues afterwards of the consistence of tar. In that state it is soluble in oils. It burns with a bright flame and bituminous smell.

Retinasphaltum.

4. Retinasphaltum has hitherto been found only in Derbyshire, accompanying Bovey coal. Mr Hatchett discovered its nature. It has a pale brown ochre yellow colour, is very brittle, and breaks with a vitreous fracture. Its specific gravity is 1.135. When heated, it melts, smokes, and burns with a bright flame, and emits a fragrant odour. It is insoluble in water, but partially soluble in alcohol, potash, and nitric acid. It is composed of

Resin,	55
Asphaltum,	41
Earths,	3
	99

Pit-coal.

5. Pit-coal, one of the most useful of all the mineral productions, may be distinguished into three kinds. 1. Those that still contain vegetable principles, strictly so called, and thus give evident marks of their origin. Some yield *extractive*, others *resin*, besides charcoal and bitumen, which constitute the greatest part of their contents. The term *brown coal*, from their colour, has been applied to the greater number of coals belonging to this set. 2. *Black coal.* In them no vegetable principle can be detected, they are composed of bitumen and charcoal in various proportions, and are usually mixed with more or less of earthy matter. 3. *Glance coal.* In this set no vegetable principle, nor even bitumen, is to be found. The coal consists of charcoal pure, or contaminated with some earth. These coals have a great deal of lustre. They are heavy, and burn without emitting any flame or smoke, and only when heated to redness.

DIVISION II.

On Secondary Compounds.

Secondary compounds.

By the term *secondary compound*, is meant a combination of *primary compounds* with each other. Thus acids combine with alkalies and form *salts*; earths combine with fixed alkalies and form *glass*; oils combine with fixed alkalies and form *soap*. The secondary compounds, as far as we are at present acquainted with them, may be arranged under the five following classes:

1. Combinations of earths with each other, and with metallic oxides.

2. Combinations of earths with alkalies.

3. Combinations of acids with alkalies, earths, and metallic oxides.

4. Combinations of sulphureted hydrogen with alkalies, earths, and metallic oxides.

5. Combinations of oils with alkalies, earths, and metallic oxides.

These combinations may be distinguished by the following titles: 1. Combinations of earths; 2. Glass; 3. Salts; 4. Hydrosulphurets; 5. Soaps.

Chap. I.

Of Combinations of Earths.

Combinations of earths.

This subject is in some measure new, and has been but imperfectly investigated. The following observations are all that can be offered:

1. The earths require so violent a heat to melt them, that they are capable of resisting the most intense fires that we can raise. But in several cases the fusion is much facilitated by mixing various earths together. Thus alumina, in a pure state, is infusible, and so is a mixture of alumina and silica, or *pure clay*. But when lime is added to this substance, it melts with comparative facility. The oxide of iron also acts as a solvent when mixed with other earthy bodies, and greatly facilitates their fusion.

2. The three alkaline earths, lime, barytes, and strontian, resemble each other in their disposition to unite with the other earths. Like the alkalies, they combine with alumina and silica, but shew no affinity for magnesia nor for each other.

3. Magnesia has a marked affinity for alumina, but for none of the other earths. When magnesia and alumina are present together in solutions, alkalies throw them down in combination.

4. Alumina has an affinity for all the alkaline earths. It has also an affinity for silica. These two earths are frequently found combined in nature.

5. Silica has an affinity for the alkaline earths, for alumina, and for zirconia. Silica enters into fusion with all the earths hitherto tried except alumina.

6. Several of the earths are capable of combining likewise with metallic oxides. Hitherto only six metals in the state of oxides have been found native combined with earths. These are, 1. chromium; 2. nickel; 3. copper; 4. zinc; 5. manganese; 6. iron. Chromium constitutes the colouring matter of the *ruby*, in which mineral it is combined with alumina and magnesia. Nickel has been found only in one mineral, the *chrysoprase*, to which it gives a green colour. The same remark applies to copper, which has been found only in the *smaragdite*, and in a very small proportion. Zinc is sometimes found combined with silica in the mineral called *calamine*, which is frequently merely an oxide of zinc. The oxide of manganese is a very frequent ingredient in dark coloured stones, as *schorl*, *garnet*, &c. It is found also combined with barytes.

But it is the oxide of iron which constitutes by far the most common metallic constituent of minerals. No less than seven distinct colours, besides various shades, have been observed in minerals containing iron. These are *white*, *black*, *green*, *blue*, *red*, *yellow*, *brown*.

The oxides of iron melt when heated with barytes, lime, alumina, or silica, when they exceed the proportion of earth considerably. They render mixtures of silica and alumina fusible at a very low heat.

CHAP. II.

Of Glass.

Glass.

SILICA, when mixed with the fixed alkalies and exposed to a strong heat, enters readily into fusion. It melts also when heated along with some of the alkaline earths, as lime, provided a little alumina be present. These mixtures are very ductile while in fusion, and may be readily moulded into any shape we please. If they be suddenly cooled below the temperature at which they become solid, they retain their transparency, and assume those peculiar properties which belong to the substance called *glass*. *Glass*, then, is a combination of the fixed alkalies, or alkaline earths with silica, either alone or conjoined with alumina, brought into complete fusion, and then suddenly congealed. Metallic oxides are sometimes added; they assist the fusion like the alkalies, and communicate frequently a peculiar colour to the vitreous mass.

When glass is in fusion, the substances which enter into its composition may be considered as combined with each other, so as to form a homogeneous mass similar to water holding a variety of salts in solution. If it be cooled down very slowly, the different tendency of the constituents to assume a solid form at peculiar temperatures, will cause them to separate successively in crystals; just as the salts held in solution in water assume the form of crystals as the liquid is slowly evaporated. But if the glass be quickly cooled down to the point of congelation, the constituents have not time to separate in succession, and the glass remains the same homogeneous compound as while in a state of fusion; just as would happen to a saline solution if suddenly exposed to a cold capable of congealing it completely. Hence it appears that the vitreous quality depends entirely upon the fusibility of the mixture, and the suddenness with which it is cooled down to the point of congelation. The substance, though solid, is precisely the same as to its chemical composition as if it were still in fusion; the sudden cooling having fixed the constituents before they had time to assume a new arrangement.

All fusible mixtures of the earths proper with fixed alkalies, alkaline earths, or metallic oxides, may be made at pleasure to assume the form of glass, or the appearance which characterises stone or porcelain, according to the rate of cooling; and glass may be deprived of its vitreous form, merely by fusing it and cooling it down with sufficient slowness to enable the constituents to separate in succession. Sir James Hall found that glass (consisting of various earthy bodies) always loses its vitreous state, and assumes that of a stone, if more than a minute or two elapses while it is cooling down from complete fusion to the point at which it congeals.

There are different kinds of glass in common use for various purposes. The finest are *plate glass*, and *flint glass* or *crystal*. They are perfectly transparent, nearly colourless, heavy, and brilliant. They are composed of fixed alkali, pure siliceous sand or calcined flints, and litharge. *Crown glass* is made without lead; it consists of fixed alkali and siliceous sand, and is much lighter than flint glass. It has a distinct greenish tinge, from the oxide of iron present in the materials employed in making it. Sometimes too great a proportion of oxide of manganese is added, which gives it a purple colour. *Bottle glass* is the coarsest and cheapest kind. It consists chiefly of lime fused with silica and a little alumina, and contains so much iron and manganese as to give it a dark colour, and to diminish its transparency very much. It is much harder, stronger, and more difficultly fusible than the fine kinds of glass.

Glass answers well as a chemical vessel, as it is acted on only by a small number of re-agents. Fluoric acid corrodes it readily; so do the fixed alkalies when assisted by heat. Water, when long boiled in it, disengages some alkali from it, and occasions the separation of silica in the state of a white powder.

CHAP. III.

Of Salts.

Salts.

THE word *salt* was originally confined to *common salt*, a substance which has been known and in common use from the remotest ages. The term was afterwards generalized by chemists, and applied to all bodies which are sapid, easily melted, soluble in water, and not combustible. At length it was confined to acids, alkalies, and the combinations of these bodies with each other. At present the term is applied to all the compounds which the acids form with alkalies, earths, and metallic oxides.

Chemists have agreed to denominate the salt from the *acids* which they contain. The alkali, earth, or metallic oxide, combined with that acid, is called the *base* of the salt. Thus Glauber salt, being a compound of sulphuric acid and soda, is called a *sulphate*, and soda is called the *base* of Glauber salt. Hence it follows, that there are as many genera of salts as there are acids, and as many individual salts, or species, as there are combinations of acids with a base. Silica and some of the metallic oxides do not appear capable of combining with acids. But to compensate this, there are some acids which combine with two bases at once, and form what are called *triple salts*. Thus *tartaric acid* combines at once with *potash* and *soda*. Some salts combine with an additional dose of their acid, and others with an additional dose of their base. The first render vegetables blue, the second usually render them green. The first kind of salts are distinguished by prefixing to the usual name the preposition *super*, the second by prefixing the preposition *sub*. Thus *sulphate of potash*, denotes the salt in a state of perfect neutralization, without any excess either of acid or potash; *supersulphate of potash* is the same salt with an excess of acid; *subsulphate* of potash is the same salt with an excess of base.

As the different genera are denominated from the acids, it is obvious that there must be as many genera as there are acids. The termination of the names of these genera differs according to the acid which constitutes them. When the acid contains a maximum of oxygen, the termination of the genus is *ate*;

when it does not contain a maximum of oxygen, the termination of the genus is *ite*. Thus the salts which contain *sulphuric acid* are called *sulphates*; those which contain *sulphurous acid* are called *sulphites*. This distinction is of some consequence, because the salts differ very much according as the acid is saturated with oxygen or not. The *ites* are seldom permanent; when exposed to the air, they usually attract oxygen, and are converted into *ates*.

Every particular species of salt is distinguished by subjoining to the generic term the name of its base. Thus the salt composed of sulphuric acid and soda, is called *sulphate of soda*. Triple salts are distinguished by subjoining the names of both the bases connected by hyphens. Thus the salt composed of tartaric acid, potash, and soda, is called *tartrate of potash-and-soda*. Sometimes, instead of this, one of the bases is prefixed to the name by way of adjective. Thus, *soda-muriate of rhodium* means the triple salt composed of muriatic acid, soda, and the oxide of rhodium. Sometimes the name of the base prefixed is altered a little; as, *ammonia-sulphate of magnesia* (*sulphate of magnesia-and-ammonia*); *ferruginous sulphate of zinc* (*sulphate of zinc-and-iron.*)

The salts naturally divide themselves into two classes. Those which contain an alkali or earth for their base, derive their chief properties from the acids, and are properly enough characterised by the name of the acids applied to the names of the genera. But those which have for their base a metallic oxide, derive their characteristic properties from that base, and ought therefore to be arranged according to it. We shall therefore divide this Chapter into two Sections; in the first, we shall treat of the salts with alkaline and earthy bases; in the second, of the salts with metallic bases.

SECT. I. *Of Alkaline and Earthy Salts.*

Alkaline and earthy salts.

As the genera of these salts (derived from their acids) are very numerous, it will be advantageous to the learner, if we subdivide them into sets according to their properties. This is attempted in the following Table.

I. Incombustible Salts.
  a. Not altered when heated with charcoal.
    1. Muriates.
    2. Fluates.
    3. Borates.
    4. Phosphates.*
  b. Decomposed without combustion when heated with charcoal.
    1. Sulphates.
    2. Carbonates.
  c. Set fire to charcoal, or yield oxygen gas by heat.
    1. Nitrates.
    2. Nitrites.
    3. Hyper-oxymuriates.
    4. Arseniates.
    5. *Molybdates.*
    6. *Tungstates.*
    7. *Chromates.*
    8. *Columbates.*†
II. Combustible Salts.
  a. Acids partially dissipated by heat, leaving salts in *ate*.
    1. Sulphites.
    2. Phosphites.
  b. Acids entirely dissipated by heat, leaving the base and charcoal.
    + Acids partly sublimed unaltered.
    1. Acetates.
    2. Succinates.
    3. Moroxylates.
    4. Benzoates.
    5. Camphorates.
    ++ Acids wholly decomposed.
    6. Oxalates.
    7. Mellates.
    8. Tartrates.
    9. Citrates.
    10. Kinates.
    11. Saccolates.
    12. Urates.
    13. Sebates.
    14. Malates.
    15. Formiates.
    16. Suberates.
    +++ Anomalous.
    17. Gallates.
    18. Prussiates.

Let us take a view of these genera in their order.

GENUS I. *Muriates.*

Muriates.

The muriates are all soluble in water, and several of them likewise in alcohol. When mixed with sulphuric acid they effervesce, and white acrid fumes with the odour of muriatic acid are exhaled.

We are but imperfectly acquainted with these bodies. Many of the compounds hitherto considered as muriates, have been shewn by Mr Davy to be compounds of chlorine, and a metallic body. Thus *common salt* is a compound of chlorine and sodium. The following are the only salts which we know at present to be muriates.

Sp. 1. *Muriate of Ammonia.* This salt was named *sal ammoniac*, because it was found native near the temple of Jupiter Ammon in Africa. It is usually in the form of hard elastic cakes. But by solution and evaporation it may be obtained crystallized in long four-sided pyramids. It deliquesces a little when exposed to moist air. It is soluble in about thrice its weight of water, and in about 75 parts of alcohol. When heated, it sublimes without decomposition, in a white smoke.

Sp. 2. *Muriate of Magnesia.* This salt exists in sea-water. It is not easily crystallized, but when its solution, properly concentrated, is exposed to a sudden cold, it may be obtained in small needles. Its taste is very bitter, hot, and biting. It dissolves in about half its weight of water, and in about twice its weight of pure alcohol. When exposed to the air, it speedily deliquesces. A strong heat decomposes it. When dried in a high temperature, it is very caustic.

---

* The phosphates are decomposed when violently heated with charcoal, but the temperature required is so high that the decomposition cannot be effected in ordinary fires. Except the phosphate of ammonia, which is decomposed pretty easily.

† The nitrate and hyperoxymuriate of ammonia are combustible alone. They are completely dissipated when heated. The genera in italics are placed from analogy only.

Sp. 3. *Muriate of Ammonia-and-Magnesia.* This salt is obtained when the solutions of the two last salts are mixed together. Its crystals are small and irregular, its taste bitter and ammoniacal. It dissolves in about six times its weight of cold water.

Sp. 4. *Muriate of Alumina.* This salt is always in the state of a supermuriate. It hardly crystallizes, being always either gelatinous or in the state of a white mass. Water dissolves about four times its weight of it. It speedily deliquesces in the air. Alcohol dissolves at least half its weight of this salt. When heated, it melts and loses its acid.

Sp. 5. *Muriate of Yttria.* This salt does not crystallize, but runs to a jelly. It melts in a gentle heat, and attracts moisture very rapidly from the atmosphere.

Sp. 6. *Muriate of Glucina.* This salt has a sweet taste, and readily crystallizes.

Sp. 7. *Muriate of Zirconia.* This salt is transparent, and crystallizes in needles, which effloresce in the air. It is very soluble in water and in alcohol. Heat decomposes it with facility.

The following Table exhibits the composition of these salts according to the most accurate experiments hitherto made:

Muriates of	Constituents.		
	Acid.	Base.	Water.
Ammonia	100	64.6	75.4
Magnesia	100	89.8	99.3
Alumina	100	100	135

The last species has not hitherto been analysed.

Genus II. *Fluates.*

Fluates.

Most of these salts are but sparingly soluble in water, and hitherto they have been but superficially examined. When sulphuric acid is poured on them, they exhale acrid fumes, which readily act upon glass and corrode it.

Sp. 1. *Fluate of Potash.* This salt is hardly known. It is said to crystallize when pure. It has but little taste, dissolves readily in water, and melts when heated. It combines readily with silica, and forms a white powder, loose like chalk, containing an excess of acid.

Sp. 2. *Fluate of Soda.* This salt crystallizes in cubes. Its taste is bitter and astringent. It is sparingly soluble in water. When heated, it decrepitates and melts into a transparent globule.

Sp. 3. *Fluate of Ammonia.* This salt crystallizes, and may be sublimed without decomposition.

Sp. 4. *Fluate of Alumina.* This salt does not crystallize, but is easily obtained in the state of a jelly. Its taste is astringent, and it always contains an excess of acid.

The remaining fluates are insoluble in water.

Sp. 5. *Fluate of Magnesia.* When this salt contains an excess of acid, it may be obtained in dodecahedrons. Heat does not decompose this salt.

Sp. 6. *Fluate of Lime.* This salt occurs native in abundance, and is the only fluate that has been accurately examined. It is usually crystallized in cubes, sometimes in octahedrons. It has no taste, nor is it altered by exposure to the air. Its specific gravity is 3.15. When heated, it decrepitates and phosphoresces strongly. When strongly heated, it melts into transparent glass. According to Dr Thomson's analysis, it is composed of 32⅔ acid and 67⅓ lime.

Sp. 7. *Fluate of Barytes.* This is a white tasteless powder, not hitherto examined.

Sp. 8. *Fluate of Alumina-and-Soda.* This salt has been found in Greenland, and is called *cryolite* by mineralogists. Its colour is greyish white. It has some transparency. It breaks into cubic fragments. Its specific gravity is 2.950. It is brittle and softer than fluate of lime. It is composed of

Acid and water,	40
Soda,	36
Alumina	24
	100

Sp. 9. *Fluate of Silica.* Fluoric acid, as usually obtained, contains, in solution, a quantity of silica. When kept in vessels not completely shut, it deposites small rhomboidal crystals of silica.

Genus III. *Borates.*

Borates.

This genus has been very imperfectly examined. All the fluates, before the blow-pipe, melt into a glass. When boiled in diluted sulphuric acid, they yield small scales of boracic acid.

Sp. 1. *Borate of Potash.* This salt crystallizes in four-sided prisms. It has been very little examined.

Sp. 2. *Borate of Soda.* This salt may be formed by saturating borax with boracic acid. It is soluble in 2½ times its weight of hot water.

Sp. 3. *Borax* or *Sub-borate of Soda.* This salt is the only one of the borates which has been accurately examined. It is brought from the East Indies, and has been in common use in Europe for ages. It seems even to have been known to the ancients. It crystallizes in hexangular prisms, but is usually in roundish semi-transparent lumps. Colour white. Specific gravity 1.740. Taste styptic and alkaline. Converts vegetable blues to green. Soluble in about twenty times its weight of cold water, but more soluble in hot water. When exposed to the air, it effloresces slowly and slightly. When heated, it melts, loses its water of crystallization, and is converted into a light porous substance called *calcined borax.* In a strong heat it melts into a transparent glass, still soluble in water. It is said to be composed of

Acid,	39
Base,	17
Water,	44
	100

Sp. 4. *Borate of Ammonia.* This salt forms permanent crystals, which resemble those of borax. Heat decomposes it.

Sp. 5. *Borate of Strontian.* This salt is a white powder, and contains an excess of base.

The remaining borates are insoluble in water.

Sp. 6. *Borate of Magnesia.* This salt may be obtained in small irregular crystals. It is soluble in acetic acid. Alcohol is said to decompose it. When heated, it melts, and is not decomposed.

Sp. 7. *Borate of Lime.* This is a white powder, hardly soluble in water, and tasteless.

Sp. 8. *Borate of Barytes.* An insoluble white powder, hardly examined.

Sp. 9. *Borate of Alumina.* Scarcely soluble, and not crystallizable.

GENUS IV. *Phosphates.*

Phosphates.

The salts belonging to this genus, when heated before the blowpipe, melts into a globule of glass. They dissolve in nitric acid, without effervescence, and are precipitated from that solution by lime-water or ammonia. They amount to twelve.

Sp. 1. *Phosphate of Potash.* Of this salt there are two varieties, the *superphosphate*, long known, and the *phosphate*, not accurately discriminated till lately.

Variety 1. *Superphosphate.* This salt is formed by dissolving carbonate of potash in phosphoric acid till all effervescence cease, and then evaporating the solution. It crystallizes with difficulty in striated prisms. It is very soluble in water, and deliquesces when exposed to the air. When heated, it undergoes the watery fusion, loses its water of crystallization, and is reduced to dryness. In a high temperature it melts into a transparent glass.

Variety 2. *Phosphate.* This salt may be formed by saturating the superphosphate with potash, and exposing the mixture to heat in a platinum crucible. It is usually in the state of a white powder, tasteless, and insoluble in cold water though it dissolves in hot water. It melts easily into a transparent bead, which becomes opake on cooling. It dissolves in the nitric, muriatic, and phosphoric acids, and is not precipitated by alkalies; but when the solutions are concentrated, a precipitate falls.

Sp. 2. *Phosphate of Soda.* This salt is usually prepared by decomposing the superphosphate of lime from burnt bones with carbonate of soda. As sold by apothecaries, it is much contaminated by sulphate of soda. It crystallizes in rhomboidal prisms. Its taste is similar to that of common salt. It dissolves in four times its weight of cold water. In the air it effloresces. When heated, it undergoes the watery fusion; and, at a red heat, melts into a white enamel.

Sp. 3. *Phosphate of Ammonia.* This salt exists in urine. It is also prepared artificially in the same way as the last species. It crystallizes in four-sided prisms. Its taste is cooling, salt, and ammoniacal. It is soluble in four parts of cold water. When heated, it undergoes the watery fusion. In a strong heat the ammonia is disengaged, and the phosphoric acid melts into a glass.

Sp. 4. *Phosphate of Magnesia.* This salt may be obtained by mixing together concentrated solutions of phosphate of soda and sulphate of magnesia; in a few hours crystals of phosphate of magnesia are deposited. It crystallizes in six-sided prisms with unequal sides. It has little taste, dissolves in 15 parts of cold water, and falls to powder when exposed to the air. When heated strongly, it melts into a transparent glass.

Sp. 5. *Phosphate of Soda-and-Ammonia.* This salt, known by the name of *microcosmic salt*, may be obtained from urine. It possesses nearly the properties of a mixture of the two preceding species.

Sp. 6. *Phosphate of Ammonia-and-Magnesia.* This triple salt exists also in urine. Its crystals are four-sided transparent prisms, terminated by four-sided pyramids. It is tasteless; scarce soluble in water; and not liable to be altered by exposure to the air. In a strong heat, it loses its ammonia, and melts into a transparent glass.

The remaining phosphates are insoluble in water.

Sp. 7. *Phosphate of Lime.* This salt constitutes the basis of bones. It may be obtained by calcining bones, dissolving them in muriatic acid, and precipitating by ammonia. It is then in the state of a white powder; but it is found native, crystallized in six-sided prisms, and is distinguished among mineralogists by the name of *apatite*. It has no taste, is insoluble in water, and not altered by exposure to the air. A red heat does not alter it; but in a very violent temperature, it is converted into a kind of enamel. It dissolves in the strong acids without effervescence, and may be again precipitated by ammonia. The strong mineral acids decompose it partially, and convert it into *superphosphate of lime*, which is an acid liquid, which crystallizes in thin brilliant plates.

Sp. 8. *Phosphate of Barytes.* This is a white tasteless powder, which, in a violent temperature, melts into a grey enamel.

Sp. 9. *Phosphate of Strontian.* This is a white powder, insoluble in water, but soluble in phosphoric acid. Before the blowpipe, it fuses into a white enamel.

Sp. 10. *Phosphate of Alumina.* A white powder, but tasteless and insoluble in water.

Sp. 11. *Phosphate of Yttria.* A gelatinous mass, insoluble in water.

Sp. 12. *Phosphate of Glucina.* A white tasteless insoluble powder.

The following Table exhibits the constituents of the phosphates, according to the experiments of Richter.

Phosphate of	Acid.	Base.
Alumina	100	53.6
Magnesia	100	62.8
Ammonia	100	68.6
Lime	100	81
Soda	100	87.7
Strontian	100	135.7
Potash	100	164
Barytes	100	222

GENUS V. *Phosphites.*

Phosphites.

The salts belonging to this genus have been but little examined by chemists. When heated, they emit a phosphorescent flame. When strongly heated, they yield a little phosphorus, and are converted into *phosphates*.

Sp. 1. *Phosphite of Potash.* This salt crystallizes in four-sided prisms. Its taste is sharp and saline. It is soluble in three parts of cold water. It is not altered by exposure to the air.

Sp. 2. *Phosphite of Soda.* It crystallizes in rhomboids. Its taste is cooling and agreeable. It dissolves in two parts of cold water. It effloresces in the air. Before the blow-pipe, it gives out a fine yellow flame, and melts into a globule which becomes opake in cooling.

Sp. 3. *Phosphite of Ammonia.* It crystallizes in four-sided prisms. Its taste is sharp and saline. It dissolves in two parts of cold water. It deliquesces a little. When heated, it loses its base; emits phosphureted hydrogen gas, and phosphoric acid remains.

Sp. 4. *Phosphite of Ammonia-and-Magnesia.* This salt is sparingly soluble in water, and crystallizes.

Sp. 5. *Phosphite of Alumina.* This salt does not crystallize, but forms a glutinous mass, which dries gradually, and does not afterwards attract moisture. It is very soluble in water. Its taste is astringent.

The remaining phosphites are insoluble in water.

Sp. 6. *Phosphite of Magnesia.* This salt is usually in the state of a white powder, or of small four-sided prisms. It effloresces in the air. It is said to be soluble in 400 parts of cold water.

Sp. 7. *Phosphite of Lime.* This is a white tasteless powder, insoluble in water, but soluble in phosphorous acid, forming a superphosphite, which may be obtained in prismatic crystals by evaporation.

Sp. 8. *Phosphite of Barytes.* This is a white powder, hardly soluble in water unless there be an excess of acid.

GENUS VI. *Carbonates.*

Carbonates.

This is one of the most important of the saline genera. When muriatic or nitric acid is poured on them, they effervesce, and give out carbonic acid. When fully saturated, they do not affect vegetable blues, but the alkaline *subcarbonates* convert vegetable blues to green.

Sp. 1. *Carbonate of Potash.* Of this salt there are two varieties, the *carbonate* and *subcarbonate*.

Variety 1. *Carbonate.* This salt may be formed by causing a current of carbonic acid to pass through a solution of potash, till the salt crystallizes. It crystallizes in rhomboidal prisms, with dihedral summits. It has a very slight alkaline taste, and still gives a green colour to vegetable blues. It is soluble in four parts of cold water. Alcohol scarcely dissolves it. Exposure to air does not alter it.

Variety 2. *Subcarbonate.* This salt is obtained by exposing the preceding to a strong red heat. It contains exactly one half of the acid contained in the carbonate. It is much more soluble in water; its taste is very alkaline and caustic; and when exposed to the air, it soon deliquesces and runs into a liquid. The potash of commerce is always in the state of a subcarbonate.

Sp. 2. *Carbonate of Soda.* Of this salt, like the preceding, there are two varieties.

Variety 1. *Carbonate.* This salt occurs native in Africa, and may be formed by passing a current of carbonic acid through a solution of soda, till it ceases to absorb any more. It runs into a hard solid mass, which is not altered by exposure to the air.

Variety 2. *Subcarbonate.* What is called carbonate of soda in commerce, is nothing else than this salt. Its crystals are octahedrons, having their apexes truncated, or more commonly flat rhomboidal prisms. It dissolves in two parts of cold water. When exposed to the air, it effloresces and falls to powder. When heated, it undergoes the watery fusion, and melts in a red heat into a transparent liquid.

Sp. 3. *Carbonate of Ammonia.* Of this salt, also, there are at least two varieties.

Variety 1. *Carbonate.* This salt may be obtained by passing a current of carbonic acid through the subcarbonate dissolved in water. It crystallizes in six-sided prisms; has no smell, and much less taste than the subcarbonate. When heated, it sublimes, and is decomposed.

Variety 2. *Subcarbonate.* This salt crystallizes, but the crystals are small and irregular. Its smell and taste are similar to those of ammonia, though weaker. It is lighter than water. It is soluble in less than twice its weight of water. From the experiments of Davy, it would appear that there are different varieties of this salt, containing various proportions of acid, according to the temperatures in which it has been prepared.

Sp. 3. *Carbonate of Ammonia-and-Magnesia.* This salt may be formed by mixing together aqueous solutions of its two constituents. Its properties have not been examined.

The remaining carbonates are insoluble in water.

Sp. 5. *Carbonate of Magnesia.* Of this salt there are likewise two varieties.

Variety 1. *Subcarbonate.* This is a light white powder, constituting the magnesia of commerce.

Variety 2. *Carbonate.* It may be formed by diffusing the preceding variety in water, and passing a current of carbonic acid through the liquid. It crystallizes in six-sided transparent prisms. It has little taste. It dissolves, when in crystals, in 48 parts of cold water. It effloresces in the air, and falls to powder.

Sp. 6. *Carbonate of Lime.* This salt, under the names of marble, chalk, limestone, calcareous spar, &c. exists in great abundance in nature. It crystallizes in rhomboidal prisms, with angles of 101½° and 78½°; and no less than 616 different varieties of form have been observed and described by mineralogists. It is tasteless, insoluble in water, but soluble in a small proportion by means of carbonic acid. When heated strongly, it loses its acid, and the escape of the acid is greatly facilitated by the presence of vapour. When suddenly heated, it melts without losing its acid, and assumes a form bearing some resemblance to granular limestone.

Sp. 7. *Carbonate of Barytes.* This salt is found native, and distinguished by mineralogists by the name of Witherite. It crystallizes in double six-sided and four-sided pyramids. It is tasteless, insoluble in water, but poisonous. It is not altered by exposure to the air. When made up into a ball with charcoal, and violently heated, it loses its acid.

Sp. 8. *Carbonate of Strontian.* This salt also occurs native, usually in semi-transparent striated masses, with a greenish tinge. It is tasteless, insoluble in water, and not altered by exposure to the air. When violently heated, it loses its acid.

Sp. 9. *Carbonate of Alumina.* Water, containing carbonic acid gas, dissolves a little alumina; but when the alumina is precipitated and dried, it appears, from the experiments of Saussure, that it loses its acid. Carbonate of alumina, then, cannot exist in a dry state.

Sp. 10. *Carbonate of Yttria.* A white, tasteless, insoluble powder.

Sp. 11. *Carbonate of Glucina.* A white, soft, tasteless powder, with greasy feel.

Sp. 12. *Carbonate of Zirconia.* A white tasteless powder.

The following Table exhibits a view of the composition of these salts, as far as it has been ascertained.

Carbonate of	Acid.	Base.	Water.
Ammonia, ...	100	33.9	44.6
Magnesia, ...	100	50	50
Potash, ...	100	95.3	37
Soda, ...	100	97.4	59
Lime, ...	100	122	
Strontian, ...	100	231	
Yttria, ...	100	305.5	150
Barytes, ...	100	363	

The subcarbonates appear to contain just one half of the acid which exists in the carbonates.

GENUS VII. *Sulphates.*

Sulphates.

This genus of salts has been long known, and very carefully examined. Most of the salts in it crystallize. Their taste is usually bitter. They are insoluble in alcohol, and precipitated from water by alcohol. When heated to redness, along with charcoal, they are converted into sulphurets. All their solutions yield a white precipitate, insoluble in cold sulphuric acid, when mixed with muriate of barytes.

Sp. 1. *Sulphate of Potash.* Of this salt there are two varieties.

Variety 1. *Sulphate.* This salt is usually to be found in considerable quantity in the potash of commerce. The crystals are small, irregular, hard, and firm: usually six-sided prisms. The taste is a disagreeable bitter. It dissolves in about 16 times its weight of cold water. It is not altered by exposure to the air. In a red heat it melts, and loses about 1⅓ per cent. of its weight.

Variety 2. *Supersulphate.* This salt may be obtained by dissolving the preceding in sulphuric acid, and evaporating. Its crystals are long slender needles, or six sided prisms. Its taste is acid, and it reddens vegetable blues. When heated, it melts, and assumes the appearance of oil. A strong red heat is necessary to drive off the excess of acid, and convert it into *sulphate*.

Sp. 2. *Sulphate of Soda.* This salt is often called Glauber's salt from the name of the discoverer of it. There are two varieties of it, like the preceding.

Variety 1. *Sulphate.* This salt crystallizes in six-sided transparent prisms, terminated by dihedral summits. The sides of the prisms are usually channelled. Its taste, at first, has some resemblance to that of common salt, but it soon becomes disagreeably bitter. It dissolves in less than thrice its weight of cold water, and in less than its weight of boiling water. When exposed to the air, it loses its water, effloresces, and falls to powder. The loss of weight is about 0.56 parts. When heated, it undergoes the watery fusion. In a read heat it melts, and, according to Kirwan, loses part of its acid.

Variety 2. *Supersulphate.* This salt may be obtained by dissolving the preceding variety in sulphuric acid, and evaporating the solution. It crystallizes in large transparent rhombs, which effloresce in the air, and easily part with their excess of acid.

Sp. 3. *Sulphate of Ammonia.* This salt crystallizes in small six-sided prisms. It has a sharp bitter taste; is soluble in twice its weight of cold water, and in its weight of boiling water. When exposed to the air, it slowly attracts moisture. When heated, it decrepitates, then melts, and sublimes with some loss of its alkali. When heated nearly to redness, the greatest part of it is decomposed.

Sp. 4. *Sulphate of Magnesia.* This salt was long known by the name of *Epsom salt,* because it exists in the spring at Epsom near London. It exists also in sea water. It crystallizes in regular four-sided prisms, surmounted by four-sided pyramids or dihedral summits. The crystals refract doubly. Its taste is intensely bitter. It dissolves in its own weight of cold water. In the air it effloresces. When heated, it undergoes the watery fusion, and before the blowpipe melts with difficulty into an opake vitreous globule.

Sp. 5. *Sulphate of Potash-and-Ammonia.* This salt crystallizes in brilliant plates. Its taste is bitter, and it is not altered by exposure to the air.

Sp. 6. *Sulphate of Potash-and-Magnesia.* This salt crystallizes in rhomboidal prisms, and is not altered by exposure to the air.

Sulphate of Soda is also capable of forming triple salts with ammonia and magnesia.

Sp. 7. *Sulphate of Magnesia-and-Ammonia.* This salt crystallizes in octahedrons. Its taste is acrid and bitter. It is decomposed by heat, and is less soluble in water than either of its constituents.

Sp. 8. *Sulphate of Alumina.* This salt crystallizes in thin plates, soft and pliant, and of a pearly lustre. Its taste is astringent. It is very soluble in water, and crystallizes with difficulty.

Sp. 9. *Alum.* This is a triple salt, of which there are four varieties, namely, 1. *Sulphate of alumina-and-potash*; 2. *Sulphate of alumina-and-ammonia*; 3. *Supersulphate of ammonia-and-potash*; 4. *Supersulphate of alumina-and-ammonia.* The two last, (especially the 3d,) constitute the *alum* of commerce; the two first have been called *alum saturated with its earth,* or *aluminated alum.*

The composition of common alum was first ascertained by Vauquelin. It crystallizes in regular octahedrons. It is white, and semitransparent. Its taste is sweetish and astringent, and it reddens vegetable blues. It dissolves in about 16 parts of cold water. In a gentle heat, it undergoes the watery fusion, and by continuing the heat, it loses about 44 per cent. of water, and is called *calcined* or *burnt alum*. In a violent heat, a portion of the acid is converted into sulphurous acid, and oxygen gas. This salt, according to the analysis of Vauquelin, is usually composed of

Sulphuric acid,	30.52
Alumina, ...	10.50
Potash, ...	10.40
Water, ...	48.58
	100.00

Alum sometimes contains a little sulphate of iron mixed with it, which injures its qualities as a mordant.

The *sulphates*, or two first varieties, may be formed by boiling alumina in a solution of alum. They are tasteless powders, insoluble in water, and not altered by exposure to the air.

Sp. 10. *Sulphate of Yttria.* This salt crystallizes in flat six-sided prisms. It is not altered by exposure to the air. Its taste is astringent and sweet. It has an amethyst red colour, and dissolves in about 30 parts of cold water. At a red heat it is perfectly decomposed.

Sp. 11. *Sulphate of Glucina.* This salt is colourless. It crystallizes in needles. Its taste is very sweet, and somewhat astringent. It is very soluble in water, and the solution does not readily crystallize. When heated, it undergoes the watery fusion, and in a red heat, is completely decomposed.

Sp. 12. *Sulphate of Zirconia.* This salt is usually in the form of a white powder; though it may be obtained also crystallized in needles. It is tasteless, and insoluble in water; not altered by exposure to the air, and easily decomposed by heat.

Sp. 13. *Sulphate of Lime.* This salt occurs native, and is distinguished by the names of *gypsum* and *selenite*. It is found crystallized in octahedrons, six-sided prisms, and in lenses. It has little or no taste. It dissolves in about 460 parts of cold water. It is not altered by exposure to the air. It dissolves in sulphuric acid. When heated, it loses its water of crystallization. When mixed with a little lime, it is much used under the name of *plaster of Paris*, for forming casts, moulds, &c.

Sp. 14. *Sulphate of Barytes.* This salt is found native, and distinguished by the names of *ponderous spar, heavy spar, baroselenite.* It occurs crystallized in tables, with bevelled edges, in four sided prisms, &c. It is white, tasteless, insoluble in water, but soluble in hot sulphuric acid. It melts, when strongly heated, into a white opake globule. When made into a cake with flour, and heated to redness, it is phosphorescent.

Sp. 15. *Sulphate of Strontian.* This salt, like the preceding, occurs native in considerable quantity. It is crystallized in rhomboidal prisms. It is white, tasteless, insoluble in water, but soluble in hot sulphuric acid. In most of its properties it resembles the preceding salt, but its specific gravity is much less. The specific gravity of sulphate of barytes is at least 4.3, while that of sulphate of strontian does not exceed 3.66.

The following table exhibits the composition of the different sulphates, as far as it has been ascertained.

Sulphate of	Acid.	Base.	Water.
Ammonia	100	26.05	57
Magnesia	100	47.36	182.8
Lime	100	72.41	55.8
Soda	100	79.34	246.6
Potash	100	112.35	20
Strontian	100	138	
Barytes	100	194	

Genus VIII. *Sulphites.*

Sulphites.

The sulphites may be formed by passing a current of sulphurous acid gas through water, holding the different bases in solution or suspension. They have a disagreeable sulphureous taste. When heated, they emit sulphurous acid and water, and at last sulphur, and are converted into sulphates. When they are exposed to the air in a state of solution, they are also gradually converted into sulphates.

Sp. 1. *Sulphite of Potash.* This salt crystallizes in rhomboidal plates, white, and semitransparent. Its taste is penetrating and sulphureous. It dissolves in its own weight of cold water. In the air it loses about two per cent. of its weight, and is very slowly altered; at least in six months it still contained nearly the usual proportion of sulphurous acid. Nitric acid speedily converts it into sulphate of potash.

Sp. 2. *Sulphite of Soda.* This salt crystallizes in flat four-sided prisms. It is white and transparent. Its taste is cool and sulphureous. It dissolves in four times its weight of cold water. In the air it effloresces, and is converted into sulphate. When heated it undergoes the watery fusion.

Sp. 3. *Sulphite of Ammonia.* It crystallizes in six-sided prisms. Its taste is cool and penetrating, and it leaves a sulphureous impression in the mouth. It dissolves in its own weight of cold water. When exposed to the air it attracts moisture, and is soon converted into sulphate. When heated, a little ammonia is disengaged, and the salt then sublimes in the state of *supersulphite of ammonia.*

Sp. 4. *Sulphite of Magnesia.* It crystallizes in the form of depressed tetrahedrons. It is white and transparent. Its taste is mild, but it leaves a sulphureous impression in the mouth. When exposed to the air, it becomes opake, and is very slowly converted into sulphate. It dissolves in 20 parts of cold water. When heated, it becomes ductile like gum, and loses 45 per cent. of its weight.

Sp. 5. *Sulphite of Ammonia-and-Magnesia.* This salt crystallizes, and is less soluble in water than either of its constituents.

Sp. 6. *Sulphite of Lime.* This salt is in the state of a white powder, or if an excess of acid be added, it crystallizes in six-sided prisms, terminated by six-sided pyramids. It has little taste, dissolves in about 800 parts of water, and in the air effloresces very slowly, its surface being changed into sulphate.

Sp. 7. *Sulphate of Barytes.* This salt, like the preceding, may be obtained in crystals, by adding an excess of acid. It crystallizes in needles. It is tasteless, and nearly insoluble in water.

Sp. 8. *Sulphite of Alumina.* This salt does not crystallize. It is a white soft powder, with an earthy and sulphureous taste. It is insoluble in water, and when exposed to the air, it is slowly converted into sulphate.

The following Table exhibits the constituents of the sulphites, as far as they have been ascertained.

Sulphites of	Acid.	Base.	Water.
Magnesia	100	41	115
Ammonia	100	48.3	18.3
Soda	100	58	164
Lime	100	97.9	10.5
Potash	100	125	4.6
Alumina	100	137.5	75
Barytes	100	151	5.1

GENUS IX. *Nitrates.*

Nitrates.

All the salts belonging to this genus are soluble in water, and crystallize by cooling. When heated to redness, and charcoal powder thrown over them, a violent combustion is produced. Sulphuric acid disengages from them fumes of nitric acid. When heated, they are decomposed, and yield at first oxygen gas.

Sp. 1. *Nitrate of Potash, or Nitre.* This salt, which is of great importance, is found in warm climates, on the surface of the earth. It is collected and purified by solution and crystallization. Its crystals are six-sided prisms, terminated by six-sided pyramids. Its taste is sharp, bitterish, and cooling. It is very brittle. It dissolves in seven parts of cold water, and in less than its own weight of boiling water. Pure alcohol does not dissolve it. In a red heat it melts and congeals into an opake mass, which has been called *mineral crystal.* When kept melted, it gives out about the third of its weight of oxygen gas. It detonates most violently with charcoal. This salt constitutes the principal ingredient of gunpowder, which is a mixture of about 76 parts nitre, fifteen charcoal, and nine sulphur. The constituents are ground to a fine powder, and then mixed together with great care. The goodness of the powder depends upon the intimate mixture. Those kinds of charcoal are pitched upon which absorb the least moisture from the air.

Sp. 2. *Nitrate of Soda.* This salt crystallizes in transparent rhombs, differing but little from cubes. It has a cool sharp taste, and is rather more bitter than nitre. It dissolves in three parts of cold water, and in less than its weight of boiling water. When exposed to the air, it rather attracts moisture. Its phenomena with combustibles and heat are the same as those of the preceding species.

Sp. 3. *Nitrate of Ammonia.* This salt crystallizes in six-sided prisms, terminated by six-sided pyramids. It has a very acrid, bitter, disagreeable taste. It dissolves in twice its weight of cold water, and in half its weight of boiling water. In the air it very speedily deliquesces. When heated, it undergoes the watery fusion; but even after the water is driven off, it continues liquid at the temperature of about 400°, boils, and is decomposed, being converted into water and *nitrous oxide* gas, in the proportion of about four parts gas to three parts water. When heated nearly to redness, it burns with a kind of explosion. Hence it was formerly called *nitrum flammans.*

Sp. 4. *Nitrate of Magnesia.* This salt crystallizes in rhomboidal prisms, or small needles. Its taste is very bitter and disagreeable. It is soluble in little more than its weight of cold water. In the air it deliquesces. When heated, it undergoes the watery fusion, and speedily assumes the form of a white powder. It scarcely detonates with combustible bodies.

Sp. 5. *Nitrate of Lime.* This salt crystallizes in six-sided prisms, terminated by long pyramids. Its taste is very acrid and bitter. It dissolves in about the fourth part of its weight of cold water, and boiling water dissolves any quantity of it whatever. Boiling alcohol dissolves its own weight of it. It speedily deliquesces in the air. When heated, it readily undergoes the watery fusion. When deprived of its water of crystallization, it often has the property of shining in the dark. In this state it is called *Baldwin's phosphorus.*

Sp. 6. *Nitrate of Barytes.* This salt crystallizes in regular octahedrons, or in small brilliant plates. Its taste is hot, acrid, and austere. It is soluble in about twelve parts of cold water. When thrown upon burning coals, it decrepitates, and is converted into a dry mass. When strongly heated, the whole of its acid is dissipated, and pure barytes obtained.

Sp. 7. *Nitrate of Strontian.* This salt crystallizes in regular octahedrons, not unlike the crystals of nitrate of barytes. It has a strong, pungent, cooling taste. It is soluble in its own weight of cold water, and in little more than half its weight of boiling water. It is insoluble in alcohol. It deflagrates on hot coals. In a crucible it melts when heated. At a red heat it gives out its acid, and pure strontian remains behind. Combustibles thrown into it when red hot, burn with a lively red flame.

Sp. 8. *Nitrate of Ammonia-and-magnesia.* This salt crystallizes in fine prisms. It has a bitter, acrid, ammoniacal taste. It dissolves in about eleven parts of cold water. In the air it gradually attracts moisture, and deliquesces.

Sp. 9. *Nitrate of Alumina.* This salt crystallizes with difficulty into thin soft plates, which have but little lustre. It has an acid and astringent taste, is very soluble in water, and soon deliquesces when exposed to the air. When evaporated, it is readily converted into a gummy mass, of the consistence of honey. It is easily decomposed by heat.

Sp. 10. *Nitrate of Yttria.* This salt scarcely crystallizes. Its taste is sweet and astringent. It speedily deliquesces in the air.

Sp. 11. *Nitrate of Glucina.* This salt may be obtained in the state of a powder, but not in crystals. Its taste is sweet and astringent. It is very soluble in water, and speedily deliquesces in the air.

Sp. 12. *Nitrate of Zirconia.* This salt does not crystallize, but may be obtained in the state of a viscid mass, which dries with difficulty. It has an astringent taste. It is very sparingly soluble in water, and seems, indeed, to be partially decomposed by that liquid. When heated, it readily parts with its acid, and is decomposed.

The following Table exhibits the composition of the nitrates, as far as has been ascertained.

Nitrate of	Acid.	Base.	Water.
Ammonia	100	40.38	35.1
Magnesia	100	47.64	
Lime	100	55.70	18.7
Soda	100	73.43	
Strontian	100	116.86	105.3
Potash	100	117.7	8.1
Barytes	100	178.12	34.3

GENUS X. *Nitrites.*

Nitrites.

When the crystallized nitrates are exposed to a sufficient heat, they give out oxygen gas. If the process be stopped in time, the salts still continue neutral. But the nature of the acid is obviously changed, as it has lost oxygen. Hence by this process the nitrates are converted into nitrites. The properties of the nitrites have not hitherto been investigated, except the nitrite of potash, examined by Bergman and Scheele. It deliquesces when exposed to the air, and gives out nitrous fumes, when treated with any acid, even the acetic.

GENUS XI. *Hyperoxymuriates.*

Hyperoxymuriates.

This genus of salts was discovered by Berthollet. But except the first species, all the rest were nearly unknown till examined by Chenevix in 1802. They are formed by passing a current of oxymuriatic acid through the bases dissolved in water. When heated nearly to redness, they give out oxygen gas, and are converted into muriates. When mixed with combustibles and heated, triturated, or struck upon an anvil, they detonate with great violence.

Sp. 1. *Hyperoxymuriate of Potash.* This salt crystallizes in flat rhomboidal prisms, of a silvery whiteness. Its taste is cooling, austere, and disagreeable, somewhat analogous to that of nitre. It dissolves in 16 parts of cold, and 2½ of boiling water. It is not sensibly altered by exposure to the air. When heated nearly to redness, it gives out more than a third of its weight of oxygen gas. It detonates loudly when mixed with sulphur or phosphorus, and struck upon an anvil, or triturated in a mortar. The experiment ought not to be tried with more than a grain of the mixture. It may be made into gunpowder with sulphur and charcoal, but it is liable to explode during the preparation.

Sp. 2. *Hyperoxymuriate of Soda.* This salt is not easily obtained pure, because it is as soluble in water as the muriate of soda, with which it is mixed in the preparation. It crystallizes in cubes. It produces a sensation of cold in the mouth, and has a taste different from that of common salt. It dissolves in about three parts of cold water. In the air it deliquesces slightly. It dissolves in alcohol.

Sp. 3. *Hyperoxymuriate of Ammonia.* This salt may be formed by mixing carbonate of ammonia with an earthy hyperoxymuriate. It is very soluble in water and alcohol, and is decomposed at a moderate temperature.

Sp. 4. *Hyperoxymuriate of Magnesia.* This salt resembles the hyperoxymuriate of lime in its properties.

Sp. 5. *Hyperoxymuriate of Lime.* This salt may be formed by passing a current of oxymuriatic acid gas through lime diffused in water, and boiling phosphate of silver in the solution, filtering and evaporating. Its taste is sharp and bitter. It is very deliquescent, and dissolves copiously in alcohol.

Sp. 6. *Hyperoxymuriate of Barytes.* This salt may be obtained in the same way as the preceding species. It is soluble in four parts of cold water.

Sp. 7. *Hyperoxymuriate of Strontian.* This salt may be prepared like the preceding. It crystallizes in needles, deliquesces, and is soluble in alcohol.

The following Table exhibits a view of the constituents of the hyperoxymuriates, as far as has been ascertained.

Hyperoxymuriate of	Acid.	Base.	Water.
Magnesia	100	42.80	28.83
Soda	100	44.78	6.35
Lime	100	51.25	29.89
Strontian	100	56.52	60.87
Potash	100	67.24	4.30
Barytes	100	89.78	22.98

GENUS XII. *Arseniates.*

Arseniates.

When the salts belonging to this genus are heated along with charcoal powder, they are decomposed, and arsenic sublimes.

Sp. 1. *Arseniate of Potash.* This salt does not crystallize. It deliquesces, and changes vegetable blues to green. The *superarseniate of potash* is a transparent white salt, which crystallizes in four-sided prisms, terminated by four-sided pyramids. It is soluble in water, and gives a red colour to vegetable blues.

Sp. 2. *Arseniate of Soda.* This salt crystallizes in six-sided prisms. The superarseniate does not crystallize.

Sp. 3. *Arseniate of Ammonia.* This salt crystallizes in rhomboidal prisms. With an excess of acid it crystallizes in needles.

Sp. 4. *Arseniate of Magnesia.* This salt does not crystallize, but may be obtained in a solid gummy mass.

Sp. 5. *Arseniate of Lime.* This salt crystallizes, and is soluble in water.

Sp. 6. *Arseniate of Barytes.* This salt is insoluble in water, and cannot be crystallized.

Sp. 7. *Arseniate of Alumina.* This salt is a white powder insoluble in water.

Sp. 8. *Arseniate of Yttria.* This salt is likewise a white powder, which does not crystallize.

GENUS XIII. *Arsenites.*

Arsenites.

The term *arsenite* has been applied to the combinations of white oxide of arsenic with the salifiable bases. The alkaline arsenites are yellow-coloured masses with a nauseous odour, not crystallizable, formerly called *livers of arsenic.* The earthy arsenites are white powders nearly insoluble in water.

GENUS XIV. *Molybdates.*

Molybdates.

If into a solution of a molybdate a cylinder of tin with some muriatic acid be put, the liquid gradually assumes a deep blue colour.

Sp. 1. *Molybdate of Potash.* This salt crystallizes in small rhomboidal plates. It is bright, and has a metallic taste. It is soluble in hot water.

Sp. 2. *Molybdate of Soda.* This salt crystallizes, and is very soluble in water.

Sp. 3. *Molybdate of Ammonia.* This salt is soluble in water, and does not crystallize.

Sp. 4. *Molybdate of Magnesia.* This salt also is soluble in water, and does not crystallize.

Sp. 5. *Molybdate of Lime.* This is a white insoluble powder.

GENUS XV. *Tungstates.*

Tungstates.

These salts are combinations of yellow oxide of tungsten with the salifiable bases.

Sp. 1. *Tungstate of Potash.* This salt is soluble in water, deliquesces, and does not crystallize. Its taste is metallic and caustic.

Sp. 2. *Tungstate of Soda.* This salt crystallizes in elongated hexahedral plates. Taste acrid and caustic. Soluble in four parts of cold and two parts of boiling water.

Sp. 3. *Tungstate of Ammonia.* This salt crystallizes in needles or small plates. Its taste is metallic. It is soluble in water, and does not deliquesce.

Sp. 4. *Tungstate of Magnesia.* This salt crystallizes in small brilliant scales. It is soluble in water, and not altered by exposure to the air.

Sp. 5. *Tungstate of Lime.* This salt is found native. It is usually crystallized. The crystals are octahedrons. Colour yellowish grey, semi-transparent. It is insoluble in water, and not altered by exposure to the air.

Sp. 6 and 7. The tungstates of barytes and of alumina, are white insoluble powders scarcely examined.

GENUS XVI. *Chromates.*

Chromates.

This genus of salts has been but imperfectly examined. The salts have usually a yellow colour. The alkaline chromates and chromate of lime are soluble in water, and crystallize. Chromate of barytes appears to be insoluble.

GENUS XVII. *Columbates.*

Columbates.

This genus of salts has been very imperfectly examined. We know only the columbate of potash, which crystallizes in scales. Its taste is acrid and disagreeable.

ORDER II.

Combustible Salts.

GENUS I. *Acetates.*

Combustible Salts.

Acetates.

THE acetates are all soluble in water. Heat decomposes them, driving off and destroying the acid. When mixed with sulphuric acid and distilled, acetic acid comes over, easily distinguished by its smell.

Sp. 1. *Acetate of Potash.* This salt is usually obtained in plates, but it crystallizes regularly in prisms. It has a sharp warm taste. It deliquesces in moist air, but in dry air undergoes but little alteration. It is soluble also in alcohol. When heated it melts, and in a high temperature is decomposed.

Sp. 2. *Acetate of Soda.* This salt crystallizes in striated prisms, not unlike those of sulphate of soda. It has a sharp taste, inclining to bitter. It dissolves in rather less than three times its weight of cold water. It is not affected by exposure to the air. When heated it loses its water of crystallization, and is decomposed.

Sp. 3. *Acetate of Ammonia.* This salt, called formerly *spirit of Mindererus,* cannot easily be crystallized by evaporation, but it may be obtained in needles by slow sublimation. Its taste is similar to that of a mixture of sugar and nitre. It is very deliquescent. It melts at 170°, and sublimes at about 250°.

Sp. 4. *Acetate of Magnesia.* This salt does not crystallize. It has a sweetish taste. It is very soluble both in water and alcohol. It deliquesces in the air.

Sp. 5. *Acetate of Lime.* This salt crystallizes in needles, and has a glossy appearance like satin. Its taste is bitter and acid. It is soluble in water, and not altered by exposure to the air.

Sp. 6. *Acetate of Barytes.* This salt crystallizes in fine, transparent, prismatic needles. Its taste is acid and somewhat bitter. It dissolves in little more than its weight of water, and rather effloresces in the air. Alcohol dissolves about $\frac{1}{100}$ of its weight of it.

Sp. 7. *Acetate of Strontian.* This salt crystallizes. Its taste is not unpleasant. It dissolves in little more than its weight of cold water. It gives a green colour to vegetable blues.

Sp. 8. *Acetate of Alumina.* This salt crystallizes in needles, is very deliquescent, and has an astringent taste.

Sp. 9. *Acetate of Yttria.* This salt crystallizes in six-sided plates of an amethyst red colour, and is not altered by exposure to the air.

Sp. 10. *Acetate of Glucina.* This salt does not crystallize, but yields a gummy mass. Its taste is sweet and astringent.

Sp. 11. *Acetate of Zirconia.* This salt does not crystallize, but may be obtained in the state of a powder, which does not attract moisture from the air. Its taste is astringent. It is very soluble in water and in alcohol.

The following Table exhibits a view of the constituents of these salts, as far as they have been ascertained.

Acetates of	Acid.	Base.
Alumina	100	35.48
Magnesia	100	41.55
Ammonia	100	45.40
Lime	100	53.58
Soda	100	58.04
Strontian	100	89.80
Potash	100	108.45
Barytes	100	131.60

Genus II. *Benzoates.*

Benzoates.

This genus of salts has been so superficially examined, that a detailed description of the species cannot be given. All the benzoates examined are soluble in water, crystallize, and have a sharp saline taste. The benzoates of ammonia and alumina deliquesce, the others do not. Most of the species form feather-shaped crystals.

Genus III. *Succinates.*

Succinates.

This genus of salts is almost as little known as the preceding. Most of the succinates crystallize. Succinate of magnesia is an exception; and succinates of barytes and glucina are nearly insoluble in water.

Genus IV. *Moroxylates.*

Moroxylates.

Only two species of this genus have been examined, the moroxylates of lime and ammonia, both of which crystallize in needles, and are soluble in water.

Genus V. *Camphorates.*

Camphorates.

The salts belonging to this genus have usually a bitterish taste. When heated they are decomposed, and the acid commonly sublimes. Before the blowpipe they burn with a blue flame.

Sp. 1. *Camphorate of Potash.* This salt is white and transparent, and crystallizes in hexagons. It dissolves in 100 parts of cold, and in four parts of hot water. Alcohol also dissolves it, and burns with a deep blue flame. When heated it melts, and the acid is volatilized.

Sp. 2. *Camphorate of Soda.* This salt is white and transparent. Its crystals are irregular. It dissolves in rather more than 100 parts of cold, and in eight parts of hot water. It is soluble in alcohol. It effloresces slightly in the air.

Sp. 3. *Camphorate of Ammonia.* This salt does not readily crystallize. It is opake, and has a sharp bitterish taste. It dissolves in about 100 parts of cold, and three parts of hot water. It is soluble in alcohol. When heated it sublimes.

Sp. 4. *Camphorate of Magnesia.* This salt does not crystallize. It is white, opake, and has a bitter taste. It requires about 290 parts of water to dissolve it. Cold alcohol does not act on it, hot alcohol decomposes it, and dissolves the acid.

Sp. 5. *Camphorate of Lime.* This salt does not crystallize. Cold water dissolves very little of it; hot water dissolves about $\frac{1}{100}$th part. It is insoluble in alcohol. In the air it falls to powder. When heated it melts, and the acid is volatilized.

Sp. 6. *Camphorate of Barytes.* This salt does not crystallize. It has little taste. It is scarcely soluble in water or alcohol. It is not altered by exposure to the air. When heated it melts, and the acid is volatilized.

Sp. 7. *Camphorate of Alumina.* This salt is a white powder, with an acid, bitter, astringent taste. It dissolves in about 200 parts of cold water, and in a much smaller quantity of hot water. Hot alcohol dissolves it readily.

Genus VI. *Oxalates.*

Oxalates.

The salts belonging to this genus are easily decomposed in a red heat; water, carbonic acid, carbonic oxide, carbureted hydrogen and charcoal are evolved, and the acid destroyed. The alkaline oxalates are soluble in water, and crystallize. They combine with an excess of acid, and form super-oxalates. The earthy oxalates are insoluble in water, or nearly so. Lime water occasions a precipitate in the solution of oxalates, provided there be no great excess of acid.

Sp. 1. *Oxalate of Potash.* This salt crystallizes in flat rhomboids. Its taste is cooling and bitter. It dissolves in thrice its weight of cold water. It absorbs a little moisture from the atmosphere.

Sp. 2. *Superoxalate of Potash.* This salt is extracted from sorrel, and usually sold under the name of the *essential salt of lemons*. Its crystals are small opake parallelopipeds. It has an acid, pungent, bitterish taste. It dissolves in about ten times its weight of boiling water, but requires a much greater quantity of cold water. It is not altered by exposure to the air. It contains exactly double the quantity of acid which the oxalate of potash contains.

Sp. 3. *Quadroxalate of Potash.* This salt was lately discovered by Dr Wollaston, by digesting superoxalate of potash in nitric or muriatic acids. One half of the alkali is separated, and there remains behind a salt, which may be obtained in crystals, and which contains four times the proportion of acid that exists in oxalate of potash.

Sp. 4. *Oxalate of Soda.* This salt crystallizes, and has nearly the same taste with the oxalate of potash. When heated it falls to powder, being deprived of its water of crystallization.

Sp. 5. *Oxalate of Ammonia.* This salt crystallizes in four-sided prisms, terminated by dihedral summits. Its taste is bitter and unpleasant, somewhat similar to that of sal-ammoniac. 100 parts of cold water dissolve 4½ of this salt. It is insoluble in alcohol. When distilled, carbonate of ammonia is disengaged, a little acid sublimed, and some charcoal left behind.

Sp. 6. *Oxalate of Alumina.* This salt does not crystallize, and has a yellow colour. It has a sweet astringent taste, is soluble in water, and sparingly soluble in alcohol. It deliquesces in the air.

The remaining species are nearly insoluble in water.

Sp. 7. *Oxalate of Magnesia.* This is a tasteless white powder, not sensibly soluble in water; yet oxalate of ammonia does not occasion a precipitate when dropt into sulphate of magnesia.

Sp. 8. *Oxalate of Lime.* This is a white powder, insoluble in water, which makes its appearance when oxalate of ammonia is poured into any neutral salt with base of lime. It is tasteless, and dissolves readily in acids.

Sp. 9. *Oxalate of Barytes.* This is an insoluble, tasteless, white powder. With an excess of acid, it may be obtained crystallized in needles.

Sp. 10. *Oxalate of Strontian.* This is a white, insoluble, tasteless powder.

Sp. 11. *Oxalate of Yttria.* This is also a white, insoluble, tasteless powder.

The following Table exhibits the composition of the oxalates, as far as ascertained:—

Oxalates of	Acid.	Base.
Ammonia	100	38.2
Magnesia	100	37.6
Soda	100	69.7
Lime	100	61.2
Potash	100	102.7
Strontian	100	119.5
Barytes	100	164.3

GENUS VII. *Mellates.*

Mellates.

This genus of salts has been but imperfectly examined. The alkaline mellates are soluble in water, and crystallize. The earthy do not appear soluble, and therefore are usually in the state of flaky powders.

GENUS VIII. *Tartrates.*

Tartrates.

These salts, when exposed to a red heat, are decomposed, and the base remains in the state of a carbonate, usually mixed with charcoal. The earthy tartrates are nearly insoluble in water; the alkaline are soluble; but they combine with an excess of acid, and are converted into supertartrates, which are much less soluble than the tartrates. They readily combine with another base, and form triple salts.

Sp. 1. *Tartrate of Potash.* Of this salt there are two varieties. The first, containing an excess of acid, is usually called *tartar.* The second, which is neutral, is called *tartrate of potash*, and formerly it was called *soluble tartar*, from its greater solubility in water.

Variety 1. *Supertartrate of Potash*, or *Tartar.* This salt deposites itself on the sides of casks in which wine is kept. It is purified by solution and evaporations. It is from it that tartaric acid is usually obtained. Its crystals are small and irregular. Its taste is acid, and rather unpleasant. It is brittle, and soluble in about 60 parts of cold water. It is not altered by exposure to the air, but when kept dissolved in water is gradually decomposed. When distilled, it gives out a great deal of heavy inflammable air, and carbonic acid gas; and an acid liquor is obtained, formerly called *pyrotartarous acid*, but now known to be merely the acetic, contaminated with a little empyreumatic oil. The tartar of commerce contains about 5 per cent. of tartrate of lime.

Variety 2. *Tartrate of Potash.* This salt may be formed by saturating the preceding with potash or its carbonate. Its crystals are flat four-sided rectangular prisms, terminated by dihedral summits. It dissolves in about its own weight of cold water. Its taste is an unpleasant bitter.

Sp. 2. *Tartrate of Soda.* This salt crystallizes in needles. It is soluble in its own weight of cold water. It is capable of forming a *supertartrate.*

Sp. 3. *Tartrate of Ammonia.* This salt crystallizes in small polygonal prisms. It has a cooling bitter taste. It is very soluble in water. It is said also to be capable of forming a *supertartrate.*

Sp. 4. *Tartrate of Potash and Soda.* This salt may be formed by saturating *tartar* with carbonate of soda. It was formerly called *Rochelle salt*, and *salt of Seignette.* It crystallizes in large irregular prisms. It has a bitter taste, is very soluble in water, and effloresces when exposed to the air.

Tartar forms also a triple salt when neutralized by ammonia.

Sp. 5. *Tartrate of Magnesia.* This salt is insoluble in water, unless it contains an excess of acid. In that case it crystallizes in six-sided prisms.

Tartar forms a triple salt when neutralized by magnesia.

Sp. 6. *Tartrate of Lime.* This salt is a white powder, insoluble in cold water. It is difficult to free it from water by heat. An excess of acid renders it soluble.

Tartar forms a triple salt when neutralized by lime.

Sp. 7. *Tartrate of Barytes.* This salt is soluble; but its properties have not been ascertained.

Sp. 8. *Tartrate of Strontian.* This salt crystallizes in triangular tables. It is insipid, and nearly insoluble in water.

Tartar forms triple salts when neutralized by barytes and strontian.

Sp. 9. *Tartrate of Alumina.* This salt does not crystallize, but forms a gummy mass soluble in water. Its taste is astringent. It does not deliquesce.

Tartar forms a triple salt when neutralized by alumina.

Sp. 10. *Tartrate of Yttria.* This salt is soluble in water, but not to a great degree.

The following Table exhibits the composition of the tartrates as far as it has been ascertained.

Tartrates of	Acid.	Base.
Alumina	100	31.06
Magnesia	100	36.30
Ammonia	100	39.67
Lime	100	45.00
Soda	100	50.80
Strontian	100	78.60
Potash	100	72.41
Barytes	100	131.41

GENUS IX. *Citrates.*

Citrates.

When barytes is poured into a solution of a citrate, a precipitate appears. They are decomposed also by the mineral acids, and by oxalic and tartaric acids. When distilled, they yield traces of acetic acid. When kept dissolved in water, the acid is gradually decomposed.

Sp. 1. *Citrate of Potash.* This salt does not crystallize easily. It is very soluble in water, and readily deliquesces.

Sp. 2. *Citrate of Soda.* This salt crystallizes in six-sided prisms, not terminated by pyramids. Its taste is salt and cooling, but mild. It dissolves in less than twice its weight of water. When exposed to the air it effloresces slightly.

Sp. 3. *Citrate of Ammonia.* This salt crystallizes in elongated prisms. Its taste is cooling, and moderately saline. It is very soluble in water.

Sp. 4. *Citrate of Magnesia.* This salt is very soluble in water. It does not crystallize.

Sp. 5. *Citrate of Lime.* This is a white powder scarcely soluble in water, but with an excess of acid it may be obtained in crystals.

Sp. 6. *Citrate of Barytes.* This salt is very imperfectly insoluble in water. It may be obtained in the state of a white powder, or of silky flakes.

Sp. 7. *Citrate of Strontian.* This salt is soluble in water. It may be obtained in crystals; and is said to resemble in its properties the oxalate or tartrate of strontian.

GENUS X. *Kinates.*

Kinates.

Only one species of this genus of salts has been hitherto examined, namely *kinate of lime*, obtained by macerating yellow Peruvian bark in water, and evaporating the solution. It is white, crystallizes in rhomboidal plates, dissolves in about five times its weight of cold water, and is insoluble in alcohol. When heated sufficiently, it is decomposed, and the acid destroyed.

GENUS XI. *Saccolates.*

Saccolates.

These salts have hitherto been too superficially examined to admit of description. The alkaline saccolates are soluble in water, but the earthy are insoluble in that liquid.

GENUS XII. *Sebates.*

Sebates.

From the observations of Berzelius, it appears that the sebates approach very nearly to the benzoates in their properties.

GENUS XIII. *Urates.*

Urates.

For the best account of these salts, we are indebted to Dr Henry. They are white powders destitute of taste, and imperfectly soluble in water. Urate of ammonia is the most soluble, and urate of barytes the least soluble.

GENUS XIV. *Malates.*

Malates.

This genus of salts has also been imperfectly investigated. The alkaline malates are soluble in water, and deliquesce in the air. Malates of barytes and lime are nearly insoluble, but the latter combines with an excess of acid, and forms a supermalate of lime, which dissolves in water. This last salt is common in the vegetable kingdom. Malate of strontian dissolves in water, and malate of magnesia is very soluble in that liquid.

GENUS XV. *Formiates.*

Formiates.

These salts resemble the acetates in their properties, but they have been only superficially examined.

GENUS XVI. *Suberates.*

Suberates.

These salts have a bitter taste. They are all soluble in water, except the suberate of barytes. The earthy suberates scarcely crystallize. Most of these salts have an excess of acid.

GENUS XVII. *Gallates.*

Gallates.

The gallic acid seems scarcely capable of forming permanent salts with the salifiable bases. When the alkalies are dropt into a solution of gallic acid, it assumes a green colour. When the liquid is evaporated, the acid seems to be decomposed. Gallic acid occasions a blue or a red colour, when dropt into lime, barytes, or strontian water.

GENUS XVIII. *Prussiates.*

Prussiates.

The prussic acid combines with the salifiable bases, but the compounds have little permanency, as the acid is separated by mere exposure to the air, or by a heat of 120°. Hence these salts have been but little examined. It is capable of combining with an alkali or earth, and with a metallic oxide at the same time, and of forming triple salts, which have a great deal of permanency. The oxide of iron is the metallic oxide usually present. Of all these salts, the most important is the *prussiate of potash-and-iron*, or the *triple prussiate of potash*, as it is in common use as a re-agent. It crystallizes in cubes or parallelopipeds. It has a yellow colour, and is semi-transparent. It contains about one-fourth of its weight of oxide of iron. It has a bitter taste, and is insoluble in alcohol, though soluble enough in water.

SECT. II. *Of Metalline Salts.*

Of metalline salts.

Acids combine only with the oxides of metals: they seem incapable of uniting with metals themselves. Now most metals form more than one oxide, and acids are usually capable of combining with two oxides at least of the same metal. The properties of the salt vary a good deal according to the state of oxidizement of the oxide. Thus muriatic acid combined with the protoxide of mercury, forms a salt insoluble in water, and which acts merely as a cathartic when taken internally. The same acid, combined with the peroxide of mercury, forms a salt which is soluble in water, and constitutes one of the most virulent poisons known. To distinguish the state of oxidizement of the metal in these salts therefore is necessary. At present we shall satisfy ourselves with denoting those metalline salts that contain protoxides by the usual name; while to the names of those that contain a peroxide, the syllables *oxy* will be prefixed. Thus *sulphate of mercury* is the compound of sulphuric acid and protoxide of mercury; *oxysulphate of mercury* is the compound of the same acid, and peroxide of mercury. As there are twenty-seven metals, it is obvious that the genera of metalline salts are twenty-seven.

GENUS I. *Salts of Gold.*

Salts of gold.

The salts of gold are soluble in water, and the solution has a yellow colour. Triple prussiate of potash occasions a white precipitate in them, and the infusion of nutgalls gives them a green colour, and occasions a brown precipitate which is gold reduced. A plate of tin or muriate of tin occasions a purple precipitate. Sulphate of iron precipitates the gold in the metallic state.

Sp. 1. *Muriate of Gold.* This salt is easily obtained by dissolving gold in a mixture of one part nitric, and four parts muriatic acid. The solution takes place speedily, and with effervescence. It has a yellow colour, and when sufficiently concentrated, lets fall small yellow crystals of muriate of gold. They are four-sided prisms or truncated octahedrons, and exceedingly deliquescent. The taste of this salt is acerb, with a little bitterness. It tinges the skin of an indelible purple colour. It dissolves readily in alcohol, and seems more soluble in ether than in water. Almost all the metals throw down the gold from this salt, either in the metallic state or in that of a purple oxide. Hydrogen, phosphorus, and sulphurous acid, produce the same effect by depriving the gold of its oxygen. Muriate of tin occasions a beautiful powder, called *purple of cassius.* It is employed as a paint, and to give a red colour to glass and porcelain. According to Proust, it is a compound of three parts of the oxide of tin, and one part of gold, in the metallic state. But it seems more likely that the gold is in the state of protoxide.

Sp. 2. *Nitrate of Gold.* Nitric acid, containing a considerable proportion of nitrous gas in solution, dissolves gold, especially if it be much divided, as is the case in gold leaf. The solution has an orange colour, and cannot be evaporated to dryness without decomposition.

The other salts of gold have not hitherto been examined.

GENUS. II. *Salts of Platinum.*

Salts of platinum.

The solution of these salts in water has a brown or yellowish brown colour. No precipitate is produced by prussiate of potash or infusion of nutgalls. Sal-ammoniac occasions a copious yellow-coloured precipitate.

Sp. 1. *Nitrate of Platinum.* Nitric acid does not act upon platinum, but it dissolves its peroxide, and forms a salt not hitherto examined.

Sp. 2. *Muriate of Platinum.* This salt is obtained by dissolving platinum in aqua regia, and evaporating the solution, which is of a dark brown colour and opake. Small irregular crystals of muriate of platinum may be obtained, not more soluble in water than sulphate of lime. This salt has a disagreeable astringent metallic taste. Heat drives off the acid, and reduces the oxide to the metallic state.

The properties of the remaining species have been but imperfectly examined. Potash and ammonia are capable of combining with the salts of platinum, and forming compounds very little soluble in water. Hence a precipitate takes place when these alkalies are poured into solutions containing platinum.

GENUS III. *Salts of Silver.*

Salts of silver.

The nitric is the only acid which dissolves silver with facility, but they all combine with its oxides and form salts, most of which are but sparingly soluble in water. When the salts of silver are exposed to the action of the blow-pipe on charcoal, a globule of silver is obtained. Muriatic acid, or a muriate, occasions a white precipitate in their solutions, which becomes black when exposed to the light. The prussiates occasion a white precipitate, and the hydrosulphuret of potash a black precipitate in these solutions.

Sp. 1. *Nitrate of Silver.* There are two species of this salt; the first, which has been long known, is an *oxynitrate;* the second, recently discovered by Proust, is a *nitrate.*

1. *Oxynitrate.* Nitric acid dissolves silver with facility, nitrous gas being emitted. The solution is colourless and transparent; very heavy and very caustic. It tinges the skin of an indelible black, and is often used as a cautery. When evaporated sufficiently, it deposites crystals of oxynitrate of silver. They are usually in thin plates, transparent, and have an intensely bitter and metallic taste. It does not deliquesce, but becomes brown in a strong light. When heated, it readily melts, and congeals, when cold, into a grey mass, crystallized in needles. In this state it is cast into small cylinders, and used under the name of *lunar caustic* by surgeons, to open ulcers, and destroy fungous excrescences. It detonates when heated with combustibles, or when struck with phosphorus upon an anvil, and the silver is reduced. A moderate heat disengages the acid, and reduces the silver to the metallic state. It is composed of about seventy peroxide of silver, and thirty nitric acid.

2. *Nitrate.* This salt may be formed by boiling powder of silver in a saturated solution of oxynitrate of silver. A pale yellow coloured liquid is obtained, which contains nitrate in solution. This salt is exceedingly soluble in water, and is not easily crystallized. When sufficiently evaporated, it congeals entirely into a solid mass. When exposed to the air, or mixed with nitric acid, it speedily absorbs oxygen, and is converted into oxynitrate.

Sp. 2. *Hyperoxymuriate of Silver.* This salt may be obtained by boiling phosphate of silver in hyperoxymuriate of alumina. It is soluble in two parts of warm water; as the solution cools it crystallizes in small rhomboids, opake and dull like nitrate of lead. It is soluble in alcohol. When exposed to a moderate heat, oxygen gas is given out and muriate of silver remains. When mixed with sulphur, and struck upon an anvil, it detonates with prodigious violence.

Sp. 3. *Sulphate of Silver.* This salt may be formed by boiling powder of silver in sulphuric acid. A white mass is obtained, soluble in diluted sulphuric acid, and yielding crystals by evaporation. The crystals are small prisms. They dissolve in about 87 parts of water. They dissolve also in nitric acid. They melt when heated, and are easily decomposed, the silver being reduced. It is composed of about 17.4 acid and 82.6 peroxide of silver.

Sp. 4. *Sulphate of Silver.* This salt may be obtained by mixing sulphate of ammonia and nitrate of silver. It is a white powder, scarcely soluble in water, and having an acrid metallic taste. In the light it becomes brown. When heated it is decomposed, and the silver reduced.

Sp. 5. *Phosphate of Silver.* This is a white powder, insoluble in water, but soluble in nitric acid.

Sp. 6. *Carbonate of Silver.* This is a white insoluble powder, which becomes black when exposed to the light.

Sp. 7. *Fluate of Silver.* This is a white powder, insoluble in water.

Sp. 8. *Borate of Silver.* This likewise is a white insoluble powder.

Sp. 9. *Acetate of Silver.* This salt crystallizes in small prisms, easily soluble in water. When heated it swells, and yields a portion of ethereal liquor. The silver is reduced.

Sp. 10. *Benzoate of Silver.* This salt is soluble in water, and does not deliquesce.

Sp. 11. *Succinate of Silver.* This salt crystallizes in thin oblong radiated prisms.

Sp. 12. *Oxalate of Silver.* This is a white powder, scarcely soluble in water, insoluble in alcohol, but soluble in nitric acid.

Sp. 13. *Tartrate of Silver.* This salt is soluble in water.

Sp. 14. *Citrate of Silver.* This salt is insoluble in water. It is decomposed by nitric acid.

Sp. 15. *Saccolate of Silver.* A white insoluble powder.

Sp. 16. *Malate of Silver.* A white powder.

Sp. 17. *Arseniate of Silver.* An insoluble brown powder.

Sp. 18. *Chromate of Silver.* A beautiful crimson powder, which becomes purple when exposed to the light.

Sp. 19. *Molybdate of Silver.* A white flaky powder.

GENUS IV. *Salts of Mercury.*

Salts of mercury.

Mercurial salts when strongly heated are volatilized, and traces of mercury may sometimes be observed. The prussiates occasion in them a white precipitate; hydrosulphuret of potash, a black precipitate; and infusion of nutgalls, an orange yellow precipitate.

Sp. 1. *Nitrate of Mercury.* There are two species of this salt, first correctly distinguished by Bergman, namely the *nitrate* and *oxynitrate.*

1. *Nitrate.* This salt is obtained by dissolving mercury in diluted nitric acid without the assistance of heat. The solution is colourless, very heavy, and caustic. It tinges the skin indelibly black. It crystallizes in transparent octahedrons, having their angles truncated. Sulphureted hydrogen gas passed through the solution of this salt, reduces the mercury, which separates in combination with sulphur. Muriate of tin throws down the base in the state of running mercury.

2. *Oxynitrate.* This salt is formed when nitric acid is made to dissolve mercury with the assistance of heat; provided an excess of mercury be not present. By continuing the heat, the solution passes into a yellow coloured crystalline mass. When diluted with water, a white or yellow powder separates, which is a *suboxynitrate of mercury.*

Sp. 2. *Hyperoxymuriate of Mercury.* Mr Chenevix obtained this salt by passing a current of oxymuriatic acid through water, in which red oxide of mercury was diffused. By evaporating the solution, crystals of *oxymuriate* and *hyperoxymuriate of mercury* were deposited. The latter were picked out and purified by a subsequent crystallization. This salt is soluble in about four parts of water.

Sp. 3. *Sulphated Mercury.* Of this salt there are two species, the *sulphate* and *oxysulphate.*

1. *Sulphate.* This salt may be obtained by boiling over mercury, sulphuric acid diluted with its own bulk of water. Very little sulphurous acid gas is disengaged. By evaporation the salt is obtained in small prismatic crystals. It dissolves in 500 parts of cold water, and is not altered by exposure to the air. The alkalies throw down a dark-coloured sub-sulphate of mercury, when poured into a solution of this salt. The sulphate of mercury is composed of 12 acid, 83 protoxide, and 5 water.

2. *Oxysulphate.* When three parts of sulphuric acid are boiled on two parts of mercury, the whole, by continuing the heat, is converted into *oxysulphate.* This salt crystallizes in small prisms. When neutral, its colour is a dirty white; but when in the state of *super-oxysulphate,* it is of a fine white. The neutral salt is not altered in the air, the super-oxysulphate deliquesces. It is composed of 31.8 acid, 63.8 peroxide, 4.4 water. When water is poured upon this salt, it is decomposed and converted into *super-oxysulphate,* which dissolves, and *sub-oxysulphate,* which remains in the state of a beautiful yellow powder. This sub-salt is used as a pigment, and was formerly known by the name of *turpeth mineral.* It is composed of 15 acid and 85 peroxide.

Sp. 4. *Phosphate of Mercury.* This salt may be formed by mixing together the solutions of nitrate of mercury and phosphate of soda. It is a white powder, insoluble in water, lately introduced into medicine, and composed of 28.5 acid, 71.5 peroxide.

There seems to be no such salt as *phosphite of mercury.*

Sp. 5. *Carbonate of Mercury.* A white insoluble powder.

Sp. 6. *Fluate of Mercury.* A white insoluble powder.

Sp. 7. *Borate of Mercury.* A yellow insoluble powder.

Sp. 8. *Acetated Mercury.* Of this salt there are two species, the *acetate* and *oxacetate.*

1. *Acetate.* This salt may be obtained by mixing together solutions of nitrate of mercury and acetate of potash. Its crystals are plates of a silvery whiteness. It has an acrid taste, is insoluble in alcohol, and scarcely soluble in water.

2. *Oxacetate.* This salt may be formed by dissolving red oxide of mercury in acetic acid. It is a yellow mass, which does not crystallize, and soon deliquesces in the air.

Sp. 9. *Succinate of Mercury.* This salt crystallizes, and is soluble in water.

Sp. 10. *Benzoate of Mercury.* A white powder, insoluble in water, and very sparingly soluble in alcohol.

Sp. 11. *Oxalate of Mercury.* A white powder, scarcely soluble in water, which blackens when exposed to the light. It detonates when heated.

Sp. 12. *Mellate of Mercury.* A white powder.

Sp. 13. *Tartrate of Mercury.* An insoluble white powder, becoming yellow when exposed to the air.

Sp. 14. *Citrate of Mercury.* A white mass, scarcely soluble in water.

Sp. 15. *Prussiate of Mercury.* This salt may be formed by boiling red oxide of mercury and prussian blue in water. It crystallizes in four-sided prisms, terminated by four-sided pyramids. Its taste is acrid and metallic. It is white, and soluble in water.

Sp. 16. *Arseniate of Mercury.* A yellow insoluble powder.

Sp. 17. *Molybdate of Mercury.* A white flaky powder.

Sp. 18. *Chromate of Mercury.* An insoluble powder, of a fine purple colour.

GENUS V. *Salts of Palladium.*

Salts of palladium.

The salts of this metal are almost all soluble in water, and the solution has a fine red colour. Prussiate of potash occasions a dirty yellowish brown precipitate, hydrosulphuret of potash, and the alkalies, an orange-yellow precipitate when poured into solutions of these salts. Neither nitrate of potash nor sal ammoniac occasions any precipitate in them. Nitric, muriatic, and sulphuric acid, digested on palladium, acquire a red colour. But the true solvent of that metal is nitro-muriatic acid. The salts of palladium are not yet sufficiently known to admit of a particular description.

GENUS VI. *Salts of Rhodium.*

Salts of rhodium.

The solutions of these salts are red. Prussiate of potash, hydrosulphuret of potash, sal ammoniac, and alkaline carbonates, occasion no precipitate in them. But the pure alkalies throw down a yellow powder, soluble in an excess of alkali.

GENUS VII. *Salts of Iridium.*

Salts of iridium.

These salts are soluble in water. The solution is at first green, but becomes red when concentrated in an open vessel. Neither prussiate of potash nor infusion of nutgalls occasion any precipitate, but they render the solutions of iridium colourless.

GENUS VIII. *Salts of Osmium.*

Salts of osmium.

This genus of salts is still entirely unknown.

GENUS IX. *Salts of Copper.*

Salts of copper.

Most of these salts are soluble in water. The solution is blue or green, or at least it acquires these colours when exposed to the air. When ammonia is poured into these solutions, they assume a deep blue colour. Prussiate of potash occasions a greenish yellow precipitate, hydrosulphuret of potash a black precipitate, and gallic acid a brown precipitate in these solutions. A plate of iron or zinc put into these solutions precipitates the copper in the metallic state.

Sp. 1. *Nitrate of Copper.* Nitric acid attacks copper with some violence, nitrous gas is emitted, and the metal dissolved. By evaporation, the salt crystallizes in parallelopipeds. It has a blue colour, its taste is acrid and metallic, and it is exceedingly caustic. It is very soluble in water, and speedily deliquesces in the air. When heated, it undergoes the watery fusion; and, if the heat be increased, the acid is driven off, and the black oxide of copper remains in a state of purity. It detonates feebly on burning coals. It detonates when mixed with phosphorus and struck upon an anvil. When moistened and wrapt up in tin-foil, it sets the tin on fire. It is composed of 16 acid, 67 oxide, and 17 water.

Sp. 2. *Hyperoxymuriate of Copper.* This salt may be formed by passing a current of oxymuriatic acid through water, containing oxide of copper diffused through it.

Sp. 3. *Muriated Copper.* Of this salt there are two species, the *muriate* and *oxymuriate.*

Sp. 4. *Sulphate of Copper.* This salt has been long known, and in commerce is distinguished by the names of *blue vitriol* or *blue copperas.* It crystallizes in oblique parallelopipeds, has a blue colour, a styptic metallic taste, and is employed as a caustic. It is soluble in about four parts of cold water. When exposed to the air, it effloresces very slightly. By heat it is decomposed, and black oxide of copper remains. It reddens vegetable blue, and is, in fact, a supersulphate. The real sulphate crystallizes in four-sided prisms, terminated by pyramids. This salt is composed of 49.1 acid, and 50.9 oxide.

Sulphuric acid does not seem capable of combining with protoxide of copper.

Sp. 5. *Sulphite of Copper.* When sulphite of soda and sulphite of copper are mixed, whitish green crystals of sulphite of copper are deposited. They are sparingly soluble in water.

Sp. 6. *Phosphate of Copper.* A bluish green powder, insoluble in water.

Sp. 7. *Carbonate of Copper.* A beautiful apple green powder, insoluble in water. It is often found native, and is distinguished by mineralogists by the name of *malachite.*

Sp. 8. *Fluate of Copper.* This salt crystallizes in cubes of a blue colour.

Sp. 9. *Borate of Copper.* A green powder, scarcely soluble in water.

Sp. 10. *Acetate of Copper.* This salt was known to the ancients. It is sometimes called *verdigris*; though that name is more frequently applied to a *subacetate* of copper. It crystallizes in four-sided truncated pyramids. Its colour is a beautiful bluish green. Its taste is metallic and nauseous; and, like all the salts of copper, it is poisonous. It is sparingly soluble in cold water, but boiling water dissolves about one-third of its weight of it. It is soluble also in alcohol. When exposed to the air, it effloresces. When distilled, it yields acetic acid in considerable quantity. It is composed, according to Proust, of 61 acid and water, and 39 oxide of copper.

Sp. 11. *Succinate of Copper.* Small green crystals, not yet examined.

Sp. 12. *Benzoate of Copper.* Deep green crystals, sparingly soluble in water, and insoluble in alcohol.

Sp. 13. *Oxalate of Copper.* A green-coloured salt, scarcely soluble in water.

Sp. 14. *Tartrate of Copper.* Bluish green crystals, sparingly soluble in water.

Sp. 15. *Citrate of Copper.* Light green crystals.

Sp. 16. *Arseniate of Copper.* This salt is precipitated in the state of a bluish white powder, when arseniate of potash is poured into sulphate of copper. It is insoluble in water, unless it contains an excess of acid. It has been found native in Cornwall, in crystals, and has been analysed by Chenevix. There are five varieties of it, differing in the proportion of acid and oxide, in the figure of their crystals, and in colour.

The oxide of copper likewise combines with white oxide of arsenic, and forms a green powder, usually known by the name of *Scheele's green.*

GENUS X. *Salts of Iron.*

Salts of iron.

Most of the salts of iron are soluble in water; the solution has a green, or yellowish, or reddish colour, according to the state of oxidizement of the iron. Prussiate of potash throws down from these solutions a blue powder, or at least it becomes blue when exposed to the air. Hydrosulphuret of potash occasions a black precipitate. Gallic acid and the infusion of nut-galls throws down a black or purple precipitate.

Sp. 1. *Nitrate of Iron.* Diluted nitric acid acts with great energy upon iron, a gas being extricated, which is a mixture of nitrous gas and nitrous oxide. There are two varieties of this salt.

1. *Nitrate.* This salt may be formed by dissolving iron in nitric acid of the specific gravity 1.16. The action is slow, and little gas is extricated. The iron is in the state of black oxide. The solution cannot be heated or concentrated without converting the iron into red oxide.

2. *Oxynitrate.* This salt may be formed by concentrating the preceding. The liquid assumes a red colour, and the red oxide of iron at last precipitates. The salt may be obtained in crystals, by keeping nitric acid in contact with black oxide of iron. The oxide gradually dissolves, and four-sided prisms, nearly colourless, are gradually formed. They deliquesce in the air.

Sp. 2. *Hyperoxymuriate of Iron.* This salt may be formed by passing a current of oxymuriatic acid through water, having red oxide of iron mixed with it.

Sp. 3. *Muriated Iron.* Of this salt there are two species, the *muriate* and *oxymuriate.*

1. *Muriate.* This salt may be formed by dissolving iron filings in muriatic acid, without the contact of the external air. The solution is green, and yields green coloured crystals, very soluble in water. The solution absorbs nitrous gas in great abundance. When exposed to the air, it absorbs oxygen, and the salt is converted into oxymuriate.

2. *Oxymuriate.* This salt may be formed by exposing the preceding to the atmosphere, or by dissolving red oxide of iron in muriatic acid. The solution has a dark brown colour; the salt does not crystallize, but when evaporated to dryness, leaves a yellow-coloured mass, which deliquesces, and is soluble in alcohol. When heated, oxymuriatic acid is

given out, and black oxide of iron remains still combined with muriatic acid.

Sp. 4. *Sulphated Iron.* Of this salt, likewise, there are two species, the *sulphate* and *oxysulphate.*

1. *Sulphate.* This salt was known to the ancients, and is used in considerable quantity in dyeing, and in the manufacture of ink. It is easily obtained by dissolving iron in diluted sulphuric acid, and evaporating the solution. It has a green colour, sometimes very light, sometimes very dark. In this last state it is preferred by artists. Upon what the difference depends is not accurately known. It crystallizes in rhomboidal prisms. It has a very styptic taste, and always reddens vegetable blues. It is soluble in two parts of cold, and in less than its weight of boiling water. It is insoluble in alcohol. When alkali is poured into a solution of this salt, a white powder precipitates, which is a *subsulphate of iron.* When heated, it melts, and loses its water of crystallization. In a red heat, it loses most of its acid, and is converted into a red powder, known by the name of *colcothar of vitriol,* and used in polishing glass and metallic bodies. This salt is composed of 26.7 acid, 28.3 base, and 45 water.

2. *Oxysulphate.* This salt may be formed by exposing the solution of the preceding to the open air. It has a yellowish-red colour, does not crystallize, and when evaporated to dryness, soon attracts moisture, and becomes again liquid.

Sp. 5. *Sulphite of Iron.* Iron dissolves in sulphurous acid, without the emission of much gas. The solution yields crystals of sulphite, which are soon changed into sulphate by exposure to the air.

Sp. 6. *Phosphated Iron.* Of this salt there are two species, the *phosphate* and *oxyphosphate.*

1. *Phosphate.* This salt may be obtained by mixing solutions of phosphate of soda and sulphate of iron. It precipitates in the state of a blue powder. It is tasteless, insoluble in water, but soluble in nitric acid. It is found native, crystallized in blue-coloured prisms.

2. *Oxyphosphate.* This is a white powder, insoluble in water, but soluble in acids, and precipitated by ammonia. When violently heated, it melts into an ash-coloured globule. When treated with a fixed alkali, it loses a portion of its acid, and is converted into a brown-coloured powder. In this state it is a *suboxyphosphate of iron.* It is insoluble in water, and nearly so in acids. But it dissolves in the serum of blood, and is supposed by some to give the red colour to blood.

Sp. 7. *Carbonate of Iron.* This salt may be obtained by precipitating sulphate of iron by an alkaline carbonate. It has been found native, crystallized in rhombs, somewhat transparent, of a greenish-yellow colour, and brittle. It is composed of 36 acid, 59.5 protoxide, and two water. *Rust* is frequently a carbonate of iron. Hence it effervesces when dissolved in acids.

Sp. 8. *Fluate of Iron.* Fluoric acid dissolves iron readily. The solution does not crystallize, but assumes the form of a jelly.

Sp. 9. *Borate of Iron.* A yellow powder, insoluble in water.

Sp. 10. *Acetated Iron.* Of this salt there are two species, the *acetate* and *oxacetate.*

1. *Acetate.* It may be obtained by dissolving sulphuret of iron in acetic acid. It forms green-coloured prismatic crystals, sufficiently soluble in water.

2. *Oxacetate.* A reddish-brown liquid, which does not crystallize, but is easily converted into a jelly, which deliquesces. This liquid is much used by calico-printers.

Sp. 11. *Succinate of Iron.* A brownish red powder, insoluble in water, unless there be an excess of acid present.

Sp. 12. *Benzoate of Iron.* Yellow crystals, with a sweet taste, soluble in water and in alcohol.

Sp. 13. *Oxalated Iron.* Oxalic acid attacks iron rapidly, and combines with both its oxides.

1. *Oxalate.* Prismatic crystals of a green colour, very soluble in water, with an excess of acid.

2. *Oxygenized Oxalate.* A yellow powder, scarcely soluble in water, and incapable of crystallizing.

Sp. 14. *Tartrated Iron.* The *tartrate* crystallizes, and is sparingly soluble in water; the *oxytartrate* is red, does not crystallize, but runs into a jelly.

Sp. 15. *Citrate of Iron.* A brown coloured solution, which deposites small crystals, very soluble in water.

Sp. 16. *Malate of Iron.* A brown solution which does not crystallize.

Sp. 17. *Gallate of Iron.* A deep blue or black powder, insoluble in water.

Sp. 18. *Prussiated Iron.* The *prussiate* is a white powder, the *oxyprussiate* a deep blue powder; both insoluble in water.

Sp. 19. *Arseniated Iron.* The *arseniate* is a green-coloured salt, insoluble in water, found native, crystallizes in cubes. The *oxarseniate* is a brownish-red powder, likewise insoluble in water.

Sp. 20. *Tungstate of Iron.* An insoluble powder of a grey colour.

Sp. 21. *Molybdate of Iron.* An insoluble brown powder.

Sp. 22. *Columbate of Iron.* An insoluble mineral of a dark brownish-grey colour, and a lamellated structure.

GENUS XI. *Salts of Tin.*

Salts of tin.

Most of these salts are soluble in water, and the solution is colourless, or has a brownish colour, according to circumstances. The prussiates, when dropt into these solutions, occasion a white precipitate; hydrosulphuret of potash occasions a brownish black, or a golden yellow precipitate; corrosive sublimate occasions a black or a white precipitate; infusion of nut-galls occasions no precipitate in these solutions.

Sp. 1. *Nitrated Tin.* Nitric acid acts with great violence on tin, and speedily converts it into an oxide. When the acid is much diluted, it forms a yellow coloured solution, containing *deutoxide of tin.* But when the solution is left to itself, or when it is concentrated by evaporation, the oxide of tin is precipitated. When the acid is strong, it speedily converts the metal into peroxide without dissolving any of it. During the action ammonia is formed, and remains in combination with the acid.

Sp. 2. *Muriated Tin.* Muriatic acid dissolves tin when assisted by heat, and the salt formed is muriate of tin. By evaporation it is obtained in needle-shaped crystals soluble in water, and somewhat deliquescent. It has a strong affinity for oxygen, and readily imbibes it from the atmosphere, from oxy-muriatic and nitric acids, and from various metallic oxides and salts. Hence the remarkable changes which it produces on many metallic solutions.

Sp. 3. *Sulphate of Tin.* When tin is kept in sulphuric acid, little action takes place. However, the tin is gradually oxidized, and sulphurous acid gas is emitted. The sulphate of tin, formed, may be obtained in the state of fine needles by evaporation. It may be readily obtained by pouring sulphuric acid into muriate of tin; a white powder precipitates, which is the sulphate, and which dissolves in water and crystallizes.

The *Oxysulphate of tin* does not crystallize, but assumes the form of a jelly.

Sp. 4. *Sulphite of Tin.* When tin is kept in sulphurous acid, the acid is decomposed, oxide of tin dissolved, and sulphuret of tin precipitated.

Sp. 5. *Phosphate of Tin.* A white powder insoluble in water.

Sp. 6. *Carbonate of Tin.* As far as is known, this species of salt does not exist.

Sp. 7. *Fluate of Tin.* A gelatinous solution having a very disagreeable taste.

Sp. 8. *Borate of Tin.* A white powder insoluble in water.

Sp. 9. *Acetated Tin.* The *acetate* of tin crystallizes; the *oxacetate* forms a gummy incrystallizable mass.

Sp. 10. *Succinate of Tin.* This salt crystallizes, and is soluble in water.

Sp. 11. *Benzoate of Tin.* This salt is soluble in water, but insoluble in alcohol.

Sp. 12. *Oxalate of Tin.* Prismatic crystals, soluble in water.

Sp. 13. *Arseniate of Tin.* A white insoluble powder.

GENUS XII. *Salts of Lead.*

Salts of lead.

Many of these salts are scarcely soluble in water. Those that are, form colourless solutions, which have usually a sweet taste. The prussiates occasion a white precipitate in these solutions; hydrosulphuret of potash, a black precipitate; infusion of nutgalls, a white precipitate.

Sp. 1. *Nitrated Lead.* Of this salt there are two varieties; the first, composed of yellow oxide and nitric acid, has been long known; we shall call it *oxynitrate;* the second, or *nitrate,* has been lately discovered by Proust.

1. *Oxynitrate.* This salt is easily obtained by dissolving lead in diluted nitric acid, and evaporating the solution. The crystals are sometimes tetrahedrons, having their apexes truncated; sometimes octahedrons. They are opake and white, and have a silvery lustre. Their taste is sweet and harsh. They are not altered by exposure to the air. They dissolve in less than eight parts of boiling water. When heated, it decrepitates, and in a strong heat the acid is driven off, while at the same time the oxide is partially reduced to the metallic state. This salt is composed of 66 yellow oxide, 34 acid and water.

2. *Nitrate.* This salt is obtained by boiling lead in a solution of *oxynitrate.* A portion of the lead is dissolved, and the solution acquires a yellow colour. When evaporated, the salt crystallizes in scales, and in small prisms. The oxide in Dr Thomson's trials appeared to be the yellow; but Bucholz affirms that it contains less oxygen. This salt is composed of 81.5 oxide, 18.5 acid.

Sp. 2. *Hyperoxymuriate of Lead.* This salt is obtained by passing a current of oxymuriatic acid through water, in which oxide of lead is suspended. It is more soluble than muriate of lead, and is easily decomposed.

Sp. 3. *Sulphate of Lead.* This salt may be obtained by pouring sulphuric acid, or an alkaline sulphate, into nitrate of lead. It is a white powder, insoluble in water, in alcohol, and in nitric and acetic acids. It is found native, crystallized in octahedrons. It is composed of about 25 acid and 75 yellow oxide. A hundred parts of it, according to Kirwan, contain 71 of metallic lead. It may be heated to redness in a platinum crucible without alteration, but when in contact with charcoal, it melts, and the lead is reduced.

Sp. 4. *Sulphite of Lead.* This is a tasteless white powder, insoluble in water. It is composed of about 74.5 oxide, and 25.5 acid.

Sp. 5. *Phosphate of Lead.* A white tasteless powder insoluble in water, easily obtained by pouring phosphate of soda into nitrate of lead. It is found native, usually of a green or yellow colour, and is often crystallized in six-sided prisms. It is soluble in nitric and muriatic acids, and from the last solution muriate of lead precipitates. When heated, it melts, and assumes, on cooling, a regular polyhedral form. It is composed of 18 acid and 82 yellowish oxide.

Sp. 6. *Carbonate of Lead.* This is a white powder insoluble in water, easily obtained by mixing solutions of nitrate of lead, and an alkaline carbonate. It is found native, crystallized in six-sided prisms, and in tables. It is employed as a paint, under the name of *white lead.* It is composed of $16\frac{1}{3}$ acid, and $83\frac{2}{3}$ yellow oxide.

Sp. 7. *Fluate of Lead.* A white powder insoluble in water, unless there be an excess of acid.

Sp. 8. *Borate of Lead.* A white insoluble powder. Before the blowpipe it melts into a colourless glass.

Sp. 9. *Acetate of Lead.* Of this salt there are two varieties, the *superacetate* and *acetate.*

1. *Superacetate.* This salt has been long known. It is usually distinguished by the name of *sugar of lead.* It may be obtained by dissolving acetate of lead in acetic acid. It is much used by dyers and calico-printers. Its crystals are small needles, with a glossy appearance like satin. It has a sweet and rather astringent taste. Water dissolves rather more than $\frac{1}{4}$th of its weight of this salt. It is not altered by exposure to the air. When distilled, there comes over water acidulated with acetic acid, then a yellow inflammable liquor, which has some of the properties of ether. The gases extricated are carbonic acid in considerable quantity, with a very little heavy inflammable air. This salt is composed of 26 acid, 58 yellow oxide, 16 water.

2. *Acetate.* This salt may be obtained, by boiling together in water 100 parts of sugar of lead, and 150 parts of litharge. Its taste is less sweet; it is less soluble in water than the preceding variety; and it crystallizes in plates. A solution of this salt is employed by surgeons under the name of Goulard's extract.

Sp. 10. *Succinate of Lead.* Slender foliated crystals, scarcely soluble in water, but soluble in nitric acid.

Sp. 11. *Benzoate of Lead.* This salt forms white crystals soluble in water and alcohol, and decomposed by heat.

Sp. 12. *Oxalate of Lead.* Small crystals insoluble in alcohol, and scarcely soluble in water, unless there be an excess of acid present.

Sp. 13. *Tartrate of Lead.* An insoluble white powder decomposed by a moderate heat. It is composed of 37 acid, and 63 yellow oxide.

Sp. 14. *Citrate of Lead.* A white powder, difficultly soluble in water.

Sp. 15. *Malate of Lead.* A white powder, which precipitates in fine light flakes, and is insoluble in water, but easily soluble in acetic and weak nitric acid.

Sp. 16. *Arseniate of Lead.* A white powder, insoluble in water. It is composed of 35.7 acid, and 64.3 yellow oxide.

Sp. 17. *Molybdate of Lead.* A white powder, insoluble in water. It occurs native in rhomboidal plates, of a yellow colour, and is composed of 34.7 acid, and 65.3 yellow oxide.

Sp. 18. *Tungstate of Lead.* A white insoluble powder.

Sp. 19. *Chromate of Lead.* This is a fine red powder, with a shade of yellow, tasteless, and insoluble in water. It occurs native, crystallized in four-sided prisms, and is composed of 34.9 acid, and 65.1 oxide.

GENUS XIII. *Salts of Nickel.*

Salts of nickel.

The salts belonging to this genus have been but imperfectly examined. They are generally soluble in water, and the solution has a fine green colour. Prussiate of potash dropt into them occasions a dull green precipitate, hydrosulphuret of potash a black precipitate, and the infusion of nutgalls a greyish white precipitate.

Sp. 1. *Nitrate of Nickel.* This salt crystallizes in eight-sided prisms; has a fine green colour; when exposed to the air it first deliquesces, and afterwards falls to powder, and gradually loses the whole of its acid. It is composed of 55 acid, 25 oxide, and 20 water. It dissolves in alcohol.

Sp. 2. *Muriate of Nickel.* This salt may be obtained by dissolving nickel in nitromuriatic acid, and evaporating the solution. It crystallizes irregularly, has an apple green colour, and deliquesces in the air. When heated it loses its water, and may be sublimed in the state of golden yellow flowers, which become green by absorbing water from the atmosphere. This salt is composed of 34 oxide, 11 acid, and 55 water. It is soluble in alcohol.

Sp. 3. *Sulphate of Nickel.* This salt has a fine green colour, and crystallizes in four-sided prisms, terminated by four-sided pyramids. It is soluble in three times its weight of water, and effloresces in the air. It is composed of 25.63 oxide, 29.37 acid, and 65 water.

Sp. 4. *Carbonate of Nickel.* This salt is obtained by precipitating nitrate of nickel with carbonate of potash. It is a green powder, composed of 56.4 acid and water, 43.6 oxide.

Sp. 5. *Fluate of Nickel.* A salt which yields light green-coloured crystals.

Sp. 6. *Acetate of Nickel.* A salt which forms rhomboidal crystals of a green colour. It dissolves in six times its weight of water.

Sp. 7. *Oxalate of Nickel.* A green powder, scarcely soluble in water.

Sp. 8. *Arseniate of Nickel.* A soluble salt of an apple green colour.

Sp. 9. *Molybdate of Nickel.* A white insoluble matter.

Sp. 10. *Phosphate of Nickel.* A green insoluble matter.

Sp. 11. *Borate of Nickel.* Similar to the preceding.

GENUS XIV. *Salts of Zinc.*

Salts of zinc.

Most of the salts of zinc are soluble in acids, and may be formed directly by dissolving zinc in the different acids. Their solutions are transparent and colourless. Prussiate of potash occasions a white precipitate, and infusion of nutgalls no precipitate.

Sp. 1. *Nitrate of Zinc.* Nitric acid dissolves zinc with great rapidity. The solution yields flat four-sided prisms, which deliquesce in the air. They are very soluble both in water and alcohol. When heated they melt, and, in a strong heat, the acid is driven off, and the oxide remains.

Sp. 2. *Muriate of Zinc.* Muriatic acid dissolves zinc with rapidity. The solution does not crystallize, but yields a gelatinous mass, which deliquesces in the air. When heated it sublimes, and forms a white-coloured mass composed of small needles. It is very soluble in water.

Sp. 3. *Sulphate of Zinc.* Diluted sulphuric acid dissolves zinc with rapidity. The solution, when concentrated, yields crystals of sulphate of zinc. This salt was discovered at Ramelsberg in Germany, about the middle of the 16th century, and introduced into commerce under the name of *white vitriol*. Its crystals are four-sided flat prisms. Cold water dissolves nearly 1½ times its weight of it, and boiling water dissolves any quantity whatever. When heated it melts, and, at a red heat, it parts with most of its acid. It is composed of 28.2 oxide, 25.8 acid, and 46 water. It contains an excess of acid.

Sp. 4. *Sulphite of Zinc.* Sulphurous acid dissolves zinc, and, by evaporation, two distinct sets of crystals are obtained. The first of *sulphureted sulphite*, consisting of sulphite combined with sulphur. Its crystals are four-sided prisms, soluble both in water and alcohol. In the air they become white, and deposit an insoluble powder. They absorb oxygen very slowly when exposed to the atmosphere. The *sulphite of zinc* also crystallizes. It is less acrid, but more styptic in its taste than sulphureted sulphite. It is less soluble in water, and insoluble in alcohol. When exposed to the air, it is speedily converted into sulphate.

Sp. 5. *Phosphate of Zinc.* This salt does not crystallize, but yields, when evaporated, a mass like gum arabic.

Sp. 6. *Carbonate of Zinc.* This salt may be obtained, by precipitating sulphate of zinc by an alkaline carbonate. It occurs native, and is known by the name of calamine. It is composed of one part acid, and two parts oxide.

Sp. 7. *Fluate of Zinc.* This salt is soluble in water, and does not crystallize.

Sp. 8. *Borate of Zinc.* A white powder insoluble in water.

Sp. 9. *Acetate of Zinc.* Acetic acid readily dissolves zinc. The salt crystallizes in rhomboidal or hexagonal plates of a talky appearance. Its taste is bitter and metallic. It is soluble in water, and not altered by exposure to the air. On live coals it burns with a blue flame.

Sp. 10. *Succinate of Zinc.* Foliated crystals scarcely examined.

Sp. 11. *Benzoate of Zinc.* Needle-shaped crystals soluble in water and alcohol.

Sp. 12. *Oxalate of Zinc.* A white powder scarcely soluble in water.

Sp. 13. *Citrate of Zinc.* Small brilliant crystals insoluble in water.

Sp. 14. *Arseniate of Zinc.* A white powder insoluble in water.

The tungstate, molybdate, and chromate of zinc, are also insoluble in water. The first two are white, the last orange red.

GENUS XV. *Salts of Bismuth.*

Salts of bismuth.

This genus of salts has been but imperfectly examined. The solutions of them are usually colourless, and when water is added to them, a white powder precipitates unless there be a considerable excess of acid present. Prussiate of potash occasions a white precipitate, hydrosulphuret of potash a black precipitate, and infusion of nutgalls an orange precipitate, when poured into these solutions.

Sp. 1. *Nitrate of Bismuth.* Nitric acid attacks bismuth with great violence. The solution is colourless, and deposites small white crystals, which are four-sided prisms. They attract a little moisture in the air. They detonate feebly on burning coals, loudly when triturated with phosphorus. When dissolved in water they are decomposed, and a white powder, which is a subnitrate of bismuth, is deposited.

Sp. 2. *Muriate of Bismuth.* This salt may be obtained by dissolving bismuth in nitromuriatic acid, and evaporating to dryness. It forms small prismatic crystals. It sublimes when heated, and forms a white mass, which easily melts, formerly called *butter of bismuth.*

Sp. 3. *Sulphate of Bismuth.* This salt may be obtained by heating a mixture of bismuth and sulphuric acid. A white mass remains, decomposed by water.

Sp. 4. *Sulphite of Bismuth.* A white powder, insoluble in water.

Sp. 5. *Phosphate of Bismuth.* Crystals soluble in water, and not altered by exposure to the air. The *subphosphate of bismuth* is a white insoluble powder.

Sp. 6. *Acetate of Bismuth.* It may be obtained by mixing solutions of nitrate of bismuth and acetate of potash, and heating the mixture. Small talky crystals of acetate of bismuth gradually precipitate.

Sp. 7. *Succinate of Bismuth.* Yellow crystalline plates, soluble in water.

Sp. 8. *Benzoate of Bismuth.* Needle-shaped crystals, not altered by exposure to the air, soluble in water, and very sparingly soluble in alcohol.

Sp. 9. *Oxalate of Bismuth.* A white powder, scarcely soluble in water.

Sp. 10. *Tartrate of Bismuth.* A white insoluble powder.

Sp. 11. *Arseniate of Bismuth.* A white tasteless powder, sometimes having a shade of green; insoluble in water and nitric acid, but soluble in muriatic acid.

Sp. 12. *Molybdate of Bismuth.* A white insoluble powder.

GENUS XVI. *Salts of Antimony.*

Salts of antimony.

The oxides of antimony combine but imperfectly with acids, and the salts which they form have not been very carefully examined. Their solutions have usually a brownish yellow colour, and in most cases a precipitate falls when they are diluted with water. Prussiate of potash and infusion of nutgalls throw down a white precipitate, hydrosulphuret of potash an orange-coloured precipitate.

Sp. 1. *Nitrate of Antimony.* Nitric acid attacks antimony slowly. Nitrous gas is emitted, ammonia formed, and the metal converted into white oxide. A portion of it is dissolved, but it does not yield crystals.

Sp. 2. *Sulphate of Antimony.* Sulphuric acid oxidizes antimony at a boiling heat, and converts it into a white mass, from which water separates the acid.

Sp. 3. *Sulphite of Antimony.* This compound is precipitated in the state of a white powder, by pouring sulphurous acid into the solution of antimony in muriatic acid. It has an acrid and astringent taste, melts when heated, and is decomposed.

Sp. 4. *Phosphate of Antimony.* This salt is soluble in water: it does not crystallize.

Sp. 5. *Acetate of Antimony.* Acetic acid dissolves the oxides of antimony, and forms a salt which crystallizes, and is soluble in water.

Sp. 6. *Oxalate of Antimony.* Small crystalline grains, scarcely soluble in water.

Sp. 7. *Tartrate of Antimony.* This salt does not crystallize, but readily assumes the form of a jelly.

Sp. 8. *Arseniate of Antimony.* A white powder, insoluble in water.

Sp. 9. *Tartrate of Potash-and-Antimony.* This salt, usually called *tartar emetic*, was first made known to chemists in 1631. It may be prepared by mixing together equal parts of peroxide of antimony and tartar, and boiling them in ten times their weight of water, filtering the solution and evaporating it till a pellicle forms on the surface. It deposites regular crystals of tartar emetic. This salt is white, crystallizes in regular tetrahedrons, and gradually effloresces when exposed to the air. It dissolves in about $14\frac{1}{4}$ parts of cold water, and in about two parts of boiling water. Heat decomposes it by destroying the acid. It is composed of 35.4 tartaric acid, 39.6 peroxide of antimony, 16.7 potash, and 8.3 water.

GENUS XVII. *Salts of Tellurium.*

Salts of tellurium.

Tellurium is too scarce a metal to expect that its salts should be completely examined. The fixed alkalies throw down, from their solutions, a white powder, which is re-dissolved by an excess of alkali. Prussiate of potash occasions no precipitate, hydrosulphuret of potash throws down a brown or blackish precipitate, and infusion of nutgalls a flaky yellow precipitate.

Sp. 1. *Nitrate of Tellurium.* Nitric acid readily dissolves tellurium. The solution is colourless, and not rendered turbid by water. When concentrated, it yields small crystals in needles.

Sp. 2. *Muriate of Tellurium.* Nitro-muriatic acid dissolves tellurium. Water throws down a white precipitate from the solution, which is re-dissolved by adding more water.

Sp. 3. *Sulphate of Tellurium.* Sulphuric acid dissolves tellurium. Water precipitates a white powder from the solution.

GENUS XVIII. *Salts of Arsenic.*

Salts of arsenic.

Arsenic is readily converted into an acid, and even its white oxide has acid properties. Hence it does not form permanent salts with acids. The acids, however, dissolve it. Prussiate of potash occasions a white precipitate in these solutions, and hydrosulphuret of potash a yellow precipitate, while the infusion of nutgalls produces no change.

Sp. 1. *Nitrate of Arsenic.* Nitric acid dissolves arsenic with violence, and separates a white powder scarcely soluble in water.

Sp. 2. *Muriate of Arsenic.* Muriatic acid dissolves arsenic when assisted by heat. It dissolves also the white oxide, especially if a little nitric acid be added. The muriate of arsenic may be obtained in small crystalline grains.

Sp. 3. *Sulphate of Arsenic.* Sulphuric acid oxidizes arsenic by the assistance of heat; the sulphate is a white powder very imperfectly soluble in water.

Sp. 4. *Acetate of Arsenic.* Acetic acid dissolves the white oxide of arsenic, and deposites crystals scarcely soluble in water.

GENUS XIX. *Salts of Cobalt.*

Salts of cobalt.

Most of these salts are soluble in water, and the solutions have a red colour, unless a great excess of acid be present. Alkalies precipitate a blue powder; prussiate of potash throws down a brownish yellow precipitate; hydrosulphuret of potash, a black precipitate; infusion of nutgalls, a yellowish white precipitate.

Sp. 1. *Nitrate of Cobalt.* Nitric acid dissolves cobalt when assisted by heat, and yields red prismatic crystals, which deliquesce in the air.

Sp. 2. *Muriate of Cobalt.* Muriatic acid dissolves cobalt when assisted by the presence of a little nitric acid. The solution is green, or, if there be no excess of acid, blue, but it becomes red when diluted with water. This solution forms the oldest and best known *sympathetic ink.* It is very much diluted with water. Characters drawn with it on paper in that state are colourless when cold, but acquires a fine green colour when heated. When the muriate is heated, it sublimes in grey coloured flowers, which dissolves with great difficulty in water. The solution consists of common muriate of cobalt.

Sympathetic ink.

Sp. 3. *Sulphate of Cobalt.* Sulphuric acid dissolves the peroxide of cobalt with difficulty. The solution is red, and yields needle-form crystals, consisting of rhomboidal prisms, terminated by dihedral summits. It is soluble in 24 parts of cold water, insoluble in alcohol, and not altered by exposure to the air. It is composed of 26 acid, 30 oxide, 44 water.

This salt readily combines with potash and ammonia, and forms triple salts with each.

GENUS XX. *Salts of Manganese.*

Salts of manganese.

These salts are mostly soluble in water. Alkalies throw down from them a red or white precipitate, which becomes black when exposed to the air. Prussiate of potash occasions a yellowish white precipitate, hydrosulphuret of potash a white precipitate, gallic acid produces no change.

Sp. 1. *Nitrate of Manganese.* Nitric acid dissolves the black oxide of manganese with the assistance of heat, provided a little sugar be added. The solution is colourless, and does not yield crystals.

Sp. 2. *Muriate of Manganese.* Muriatic acid readily dissolves black oxide of manganese when assisted by heat, abundance of oxymuriatic acid separating. The solution is colourless, and deposits small crystals of *muriate of manganese.* These crystals are not easily formed. When obtained, they are hard, very soluble in water, and deliquesce in the air. Muriatic acid appears also to combine with red oxide of manganese, and to form a red solution containing oxymuriate of manganese.

Sp. 3. *Sulphated Manganese.* Sulphuric acid readily dissolves the white and red oxides of manganese. Upon the black it has no action, unless it be assisted by heat. In that case, oxygen gas is emitted in abundance, and the oxide is dissolved, being converted into red or white oxide, according to circumstances. There are two combinations of sulphuric acid and the oxides of manganese; one with the *white*, and another with the *red* oxide.

1. *Sulphate.* The solution of this salt is colourless, and yields, by evaporation, rhomboidal crystals. They have a very bitter taste, and are decomposed by heat, which drives off the acid.

2. *Oxysulphate.* The solution of this salt has a red colour. It does not readily crystallize, but when evaporated, easily passes into a jelly. When evaporated to dryness, it yields red coloured saline crusts,

very soluble in water, and not altered by exposure to the air.

Genus XXI. *Salts of Chromium.*

Salts of chromium.

The salts of chromium are but very little known. For the few facts ascertained, we are indebted to Richter, Godon, and Vauquelin. Prussiate of potash occasions a brown solution in these salts; infusion of nutgalls, a brown precipitate; hydrosulphuret of potash, a green precipitate, which a few drops of nitric acid change to yellow.

When the oxide of chromium is obtained by precipitating chromate of potash by means of a hydrosulphuret, it dissolves readily in acids. The solutions have a green colour, and the compounds are easily decomposed. Nitric acid seems to convert the oxide into chromic acid. It does not appear that these solutions are capable of affording crystals. The acids hitherto tried, and found capable of dissolving oxide of chromium, are the nitric, muriatic, sulphuric, phosphoric, sulphurous, and oxalic.

Genus XXII. *Salts of Molybdenum.*

Salts of molybdenum.

The salts belonging to this genus are as imperfect as those belonging to the preceding. None of them seem capable of crystallizing. But many acids dissolve oxide of molybdenum, and the solutions are remarkable for the changes of colour to which they are liable.

Nitric acid dissolves molybdenum with difficulty. If the quantity of metal be greater than the acid can dissolve, the solution is blue; but when a small quantity of molybdenum is dissolved in a considerable proportion of acid, the solution is yellowish brown.

Muriatic acid does not attack molybdenum, but it dissolves its oxide, and forms a blue coloured solution.

Sulphuric acid dissolves molybdenum when assisted by heat, and forms a yellowish brown or a blue solution, according to the proportion of metal acted on.

Genus XXIII. *Salts of Uranium.*

Salts of uranium.

Most of these salts are soluble in water, and the solution has a yellow colour. The pure alkalies occasion in these a yellow precipitate, prussiate of potash a brownish red precipitate, hydrosulphuret of potash a brownish yellow precipitate, and infusion of nutgalls a chocolate coloured precipitate.

Sp. 1. *Nitrate of Uranium.* Nitric acid readily dissolves uranium and its oxides. The solution, when sufficiently concentrated, yields crystals of nitrate, either in hexagonal tables, or in four-sided flat prisms, with a lemon yellow colour, and greenish edges. Water dissolves more than twice its weight of this salt, and alcohol more than thrice its weight of it. These liquids, when hot, dissolve any quantity of the salt whatever. Sulphuric ether dissolves about one-fourth its weight of this salt. Nitrate of uranium deliquesces in a moist atmosphere, but when kept at the temperature of 100° it soon falls to powder. When heated it melts, and, by continuing the heat, is decomposed. This salt is composed of 61 oxide, 25 acid, and 14 water.

By exposing the nitrate to a moderate heat, it is converted into a lemon-yellow powder, insoluble in water, which is a *sub-nitrate* of uranium.

Sp. 2. *Muriate of Uranium.* Deliquescent crystals of a yellowish green colour, having the form of four-sided tables.

Sp. 3. *Sulphate of Uranium.* Sulphuric acid scarcely acts upon uranium, but it gradually dissolves its oxide, and the solution yields small crystals of a lemon-yellow colour in prisms or tables. This salt dissolves in less than its weight of cold water, and in about half its weight of boiling water. Alcohol dissolves $\frac{1}{17}$th of its weight of it. Heat decomposes it, driving off the acid and water, but a violent temperature is necessary. This salt is composed of

Acid	18
Oxide	70
Water	12
	100

Sp. 4. *Acetate of Uranium.* Acetic acid dissolves oxide of uranium, and yields beautiful crystals in the form of long slender transparent four-sided prisms, terminated by four-sided pyramids.

Genus XXIV. *Salts of Tungsten.*

Salts of tungsten.

This genus of salts is still unknown. None of them, from the difficulty of obtaining the metal in a state of purity, having been hitherto examined.

Genus XXV. *Salts of Titanium.*

Salts of titanium.

The salts of titanium are, in general, soluble in water, and the solution is colourless. The alkaline carbonates occasion a flaky precipitate in these solutions, prussiate of potash a yellowish brown precipitate, hydrosulphuret of potash a dirty bottle-green, and the infusion of nutgalls a very bulky blood-red precipitate. When a rod of tin is plunged into a solution of titanium, the liquid around it gradually assumes a fine red colour. A rod of zinc occasions a deep blue colour.

Sp. 1. *Nitrate of Titanium.* Nitric acid dissolves the carbonate of titanium, and yields transparent crystals in the form of elongated rhombs, having two opposite angles truncated, so as to represent six-sided tables.

Sp. 2. *Muriate of Titanium.* Muriatic acid dissolves the carbonate of titanium, and forms transparent cubic crystals. From the experiments of Vauquelin and Hecht, it appears that it is the peroxide of titanium only that combines with muriatic acid.

Sp. 3. *Sulphate of Titanium.* Sulphuric acid dissolves the carbonate of titanium. The solution does not crystallize, but yields, when evaporated, a white opake gelatinous mass.

Genus XXVI. *Salts of Columbium.*

Salts of columbium.

This genus of salts has been but imperfectly examined. Hatchett, Ekeberg, and Wollaston, are the only persons who have hitherto made experiments on this scarce metal. Sulphuric, nitric, and muriatic acids scarcely dissolve the oxide of columbium. The oxalic, tartaric, and citric acids dissolve it readily. The solutions appear to be transparent and colourless. Neither prussiate of potash, nor hydrosulphuret of potash, occasion any precipitate in these solutions; but infusion of nutgalls throws down an orange coloured precipitate, provided there be no excess of acid present, but a slight excess of acid prevents the precipitate from appearing.

GENUS XXVII. *Salts of Cerium.*

Salts of Cerium.

The salts of cerium have either a white or a yellow colour, according to the state of oxidizement of the metal. Their solutions in water have a sweet taste. Hydrosulphuret of potash throws down a white precipitate, prussiate of potash a milk-white precipitate, and infusion of nutgalls no precipitate whatever. The oxalate of ammonia occasions a white precipitate, which is insoluble in nitric and muriatic acids.

Sp. 1. *Nitrate of Cerium.* Nitric acid dissolves white oxide of cerium readily: the solution is colourless, crystallizes with difficulty, retains an excess of acid, and has an austere and sweet taste. It dissolves the red oxide with difficulty unless heat be applied. The solution is yellow, and yields small white crystals, which deliquesce when exposed to the air. Both of these salts are soluble in alcohol. Heat decomposes them, leaving a red coloured oxide.

Sp. 2. *Muriate of Cerium.* Muriatic acid dissolves red oxide of cerium when assisted by heat, oxymuriatic gas is exhaled, and the solution has a yellowish red colour, which becomes lighter the longer the heat is continued. The solution yields four-sided prismatic crystals of a yellowish white colour. They are soluble in alcohol, and deliquesce when exposed to the air. Their taste is astringent and sweet. Heat decomposes this salt by driving off the acid and water.

Sp. 3. *Sulphate of Cerium.* Sulphuric acid dissolves the red oxide of cerium by long digestion, an orange-coloured solution is obtained, which yields small octahedral and needle-form crystals. The colour of these crystals is partly lemon yellow, partly orange. They are scarcely soluble in water. Their taste is acid and sweet. When exposed to the air, they soon fall into a yellow powder.

Sulphuric acid dissolves the white oxide of cerium very readily. The solution is colourless, has a sweet taste, and yields crystals of sulphate of cerium.

Sp. 4. *Carbonate of Cerium.* When white oxide of cerium is precipitated from its solutions by an alkaline carbonate, carbonate of cerium is obtained. It is a granular powder of a silvery whiteness, insoluble in water, and composed of 23 acid, 65 oxide, and 12 water.

Sp. 5. *Acetate of Cerium.* Acetic acid dissolves the white oxide of cerium, and forms small sweet-tasted crystals, soluble in water, but very sparingly soluble in alcohol.

CHAP. IV.

Of Hydrosulphurets.

Hydrosulphurets.

SULPHURETED hydrogen gas possesses many of the properties of an acid, and, like acids, it combines with the salifiable bases, and forms a class of bodies called *hydrosulphurets.* These bodies are of considerable importance, as they are frequently employed in chemical analysis, and enable us to separate the metallic oxides from alkalies and earths, because they throw down almost the whole of them from their solutions in an insoluble state.

Their properties.

The hydrosulphurets are soluble in water, and the solution is colourless. When the solution is exposed to the air, it becomes green or greenish yellow. After long exposure to the air, the solution becomes again limpid and colourless, and, on examination, is found only to contain the base of hydrosulphuret combined with sulphuric acid. The solution of the hydrosulphurets precipitates almost all the metallic oxides from their solutions; iron and lead, black; antimony, orange; arsenic, yellow, &c.

How formed.

The hydrosulphurets may be formed, by dissolving or diffusing the respective bases in water, and passing a current of sulphureted hydrogen gas through the liquid till it ceases to absorb any more. The excess of gas is then driven off by heat; and the hydrosulphuret may be obtained in a solid state if required by evaporation. The yellow colour which these solutions acquire when exposed to the air, is owing to the decomposition of the sulphureted hydrogen by the gradual absorption of oxygen from the atmosphere.

Hydrosulphurets of barytes,

Sp. 1. *Hydrosulphuret of Barytes.* When sulphate of barytes is converted into sulphuret by mixing it with charcoal, and heating it red hot in a crucible, if boiling water be poured upon the black mass, and filtered while hot, the green coloured solution thus obtained yields, by evaporation, a great number of crystals. These crystals are hydrosulphuret of barytes. They are white, and have a silky lustre. They have the form of scales, and the shape cannot easily be distinguished. This substance is soluble in water, the solution has a slight tint of green, its taste is acrid and sulphureous, and when exposed to the air is readily decomposed.

Strontian,

Sp. 2. *Hydrosulphuret of Strontian.* It may be procured by the same process as the preceding hydrosulphuret, and its properties are nearly similar.

Potash,

Sp. 3. *Hydrosulphuret of Potash.* This substance is formed during the solution of sulphuret of potash, and may be obtained by evaporation. It is transparent and colourless, and crystallizes in large prisms, not unlike the figure of sulphate of soda. Its taste is alkaline, and extremely bitter. When exposed to the air it soon deliquesces into a liquor of a syrupy consistence, tinging green all bodies with which it happens to come in contact. The crystals have no smell at first, but when they have deliquesced they emit a fetid odour. They dissolve both in water and alcohol, and during the evolution the temperature sinks considerably. Acids drive off the sulphureted hydrogen with a violent effervescence.

Soda,

Sp. 4. *Hydrosulphuret of Soda.* The crystals of this substance are transparent and colourless, having the figure of four-sided prisms terminated by quadrangular pyramids. Its taste is alkaline, and intensely bitter. It is very soluble both in water and alcohol, and during the solution cold is produced. When exposed to the air it deliquesces, and acquires a green colour. Acids drive off the sulphureted hydrogen.

Lime,

Sp. 5. *Hydrosulphuret of Lime.* This substance may be formed, by passing sulphureted hydrogen gas through water, having lime suspended in it. The solution is colourless, and has an acrid and bitter taste.

Ammonia,

Sp. 6. *Hydrosulphuret of Ammonia.* This compound may be formed by passing sulphureted hydrogen through liquid ammonia. When equal parts of lime, sal ammoniac, and sulphur, mixed with a little water, are distilled in a retort, a yellow liquid is obtained, usually distinguished by the name of *fuming liquor of Boyle,* because first prepared by that philosopher. This liquid is little else than hydrosulphuret of ammonia holding an excess of ammonia in solution.

Magnesia,

Sp. 7. *Hydrosulphuret of Magnesia.* This substance may be formed, by passing a current of sulphureted hydrogen through water in which magnesia is diffused. Its properties have not been hitherto examined.

Glucina, and Yttria.

Sp. 8 and 9. *Hydrosulphurets of Glucina* and of *Yttria.* From the experiments of Klaproth and Vauquelin, we know that the hydrosulphurets do not precipitate glucina or yttria from acids. Hence it is likely that they are capable of combining with sulphureted hydrogen, though these combinations have not hitherto been examined by chemists.

Neither alumina nor zirconia combine with sulphureted hydrogen. Hence the hydrosulphurets precipitate these earths from acids.

When the alkalies and alkaline earths are mixed with sulphur and water, and boiled in a glass vessel, a brown coloured solution is obtained, formerly called *liquid liver of sulphur.* At present the term *hydrogureted sulphurets* is applied to these solutions. They are conceived to be combinations of the alkaline bases with sulphur and sulphureted hydrogen at once, and therefore to be triple compounds. The proportion of sulphureted hydrogen is often very small.

The hydrosulphurets precipitate almost all the metals from their solutions. The precipitates vary in their colour according to the metal. The following Table exhibits a view of the colours of the various precipitates in these cases, as far as the subject has been investigated.

METALS.	PRECIPITATED BY	
	Hydrosulphuret of Potash.	Hydrogureted Sulphuret of Potash.
Gold . .	Black . .	Black
Platinum .	Black . .	Black
Silver . .	Black . .	Black
Mercury .	Brown black	Brown, becoming black
Palladium .	Black	
Copper . .	Black . .	Brown
Iron . . .	Black . .	Black, becoming yellow
Nickel . .	Black . .	Black
Tin . . .	Black . .	Black
Lead . . .	Black . .	White, becoming black
Zinc . . .	White . .	White
Bismuth . .	Black . .	Black
Antimony .	Orange . .	Orange yellow
Tellurium .	Black ? . .	Deep brown or black
Arsenic .	Yellow . .	Yellow
Cobalt . .	Black . .	Black
Manganese . .	White . .	White
Chromium . .	Green	
Molybdenum	Reddish brown	
Uranium .	Brown . .	Brownish yellow
Titanium .	Bottle-green	Bluish green.
Columbium	Chocolate	
Cerium . .	Brown	

CHAP. V.

Of Soaps.

Soaps.

THE fixed oils have the property of combining with alkalies, earths, and metallic oxides, and of forming a class of compounds which have received the name of SOAPS. As these soaps differ from each other very materially, according as their base is an alkali, an earth, or a metallic oxide, it will be proper to consider each set separately.

SECT. I. *Of Alkaline Soaps.*

Alkaline soaps.

All or most of the fixed oils are capable of combining with the alkalies, and forming soap; but the differences which they produce on the qualities of the soap have only been observed in a few cases. We can only consider the different species occasioned by different alkalies.

Sp. 1. *Soap of Soda,* or *Hard Soap.* The word *soap* (*sapo*, σαπὼν) first occurs in the writings of Pliny and Galen, and was obviously derived from the old German word *sepe:* for the knowledge of this useful compound seems first to have arisen among the Gauls and Germans.

Hard soap is made by mixing soda of commerce with a sufficient quantity of lime and water to deprive it of its carbonic acid, drawing off the ley, and boiling it with a quantity of olive oil or tallow, amounting to six times the weight of the soda used. When sufficiently boiled, a quantity of common salt is added, which induces the soap to separate from the water, and to float upon the surface. Though in this country, where kelp is usually employed at least in part to furnish the soda, the quantity of common salt present from the beginning is usually sufficient without any addition. The soap is then poured into proper vessels, and when cold cut into parallelopipeds. Whale oil has been tried, but found improper for making hard soap. In this country, tallow is usually employed. In France, and the south of Europe, olive oil is used. When oil or tallow alone is used, the soap has a white colour; but it is usual to add a quantity of rosin, which gives it a yellow colour, and a softer consistence. It is then called *yellow* soap.

The appearance and properties of common soap are so well known, that it is unnecessary to describe it. The various uses to which it is applied are equally well known. It dissolves in alcohol, but is precipitated by the addition of water. With water it readily mixes, though it does not, strictly speaking, dissolve in that liquid, as most of it is separated by the filter. A specimen of white soap analysed by Darcet, Lelievre, and Pelletier, was composed of

60.94	oil,
8.56	alkali,
30.50	water.
100.00	

Sp. 2. *Soap of Potash,* or *Soft Soap.* When potash is substituted for soda, the soap never hardens by cooling, but remains always soft. Whale oil is said to be employed in the manufacture of soft soap. A little tallow is also added, which, by peculiar management, is dispersed through the soap in fine white spots. The properties of soft soap are too well known to need description. It is the only species of soap with which the ancients were acquainted. It is but little used in this country in comparison of hard soap.

Sp. 3. *Soap of Ammonia.* This soap may be formed by digesting carbonate of ammonia on soap of lime. Its taste is more pungent than that of common soap. It mixes sparingly with water, but is pretty soluble in alcohol. The substance employed as an external application by surgeons under the name of *volatile liniment,* is scarcely any thing else than this soap.

SECT. II. *Of Earthy Soaps.*

Earthy soaps.

The earthy soaps differ essentially from the alkaline, in being insoluble in water, and therefore incapable of being used as detergents. They are formed whenever a solution of common soap in water is mixed with that of an earthy salt. Hence the reason that all waters holding an earthy salt in solution are unfit for washing. They decompose the common soap, and form a soap insoluble in water. Such waters are called *hard*, and are very frequent, especially in pit wells.

All the earthy soaps are insoluble in alcohol, except soap of magnesia, which dissolves both in alcohol and fixed oils. The earthy soaps are all white, and require a considerable heat to melt them.

SECT. III. *Of Metallic Soaps.*

Metallic soaps.

The metallic soaps may be formed in the same way as the earthy soaps. They are insoluble in water, and cannot be used as detergents; but several of them are soluble in alcohol and in fixed oils. The greater number of them have a white colour; but soap of cobalt is of a leaden colour; soap of iron, reddish-brown; and soap of copper, green. Berthollet, who examined these soaps, has recommended some of them as paints.

Some of the metallic oxides, as those of mercury, lead, and bismuth, when mixed with fat oils and water, and boiled, form an intimate combination with the oil, used by surgeons under the name of *plaster*. Litharge is the metallic substance commonly used for these compounds, and olive oil answers better than any other hitherto tried. These plasters soften when heated, and adhere very strongly to the skin when spread thin upon linen or leather, but they may be drawn off by using the requisite force, without leaving any portion adhering to the skin. In these properties their excellence consists.

BOOK III.

OF AFFINITY.

Of Affinity.

HAVING taken a view of the different substances which constitute the objects of chemistry, it remains for us to make a few remarks on the force by which different bodies are united together, and kept in combination. This force has received the name of *affinity*.

All the great bodies which constitute the solar system are urged towards each other by a force which preserves them in their orbits, and regulates their motions. This force has received the name of *attraction*. Newton demonstrated that this force is the same with *gravitation*, or the force by which a heavy body is urged towards the earth.

When two bodies are brought within a certain distance, they adhere together, and require a considerable force to separate them. Hence it appears that bodies are not only attracted towards the planetary bodies, but towards each other. In all cases we find the particles of matter united together in masses, differing indeed in magnitude, but containing all of them a considerable number of particles. These particles remain united, and cannot be separated without the application of a considerable force.

Thus we see that there is a certain unknown force which urges bodies towards each other; a force which acts not only upon large masses of matter, but upon the particles of which bodies are composed. Attraction, therefore, as far as we know, extends to all matter, and exists mutually between all matter.

The change which attraction produces on bodies is a diminution of their distance. Now the distances of bodies from each other are of two kinds, either too small to be perceived by our senses, or great enough to be easily perceived and estimated. Hence the attractions of bodies, as far as regards us, naturally divide themselves into two classes. 1. Those which act at sensible distances from each other. 2. Those which act at insensible distances. It is to the second of these attractions that the term *chemical affinity* has been given.

Chemical affinity then is the attraction which exists between the particles of bodies, which urges them towards each other, and keeps them united. Now the particles of matter are of two kinds, either *homogeneous* or *heterogeneous*. By homogeneous particles are meant the particles which compose the same body; by heterogeneous, those which compose different bodies. Thus the particles of iron are homogeneous; but a particle of iron and a particle of lead are heterogeneous.

Homogeneous affinity urges the homogeneous particles towards each other, and keeps them united. It is usually denoted by the term *cohesion*, and sometimes by *adhesion*, when the surfaces of bodies only are referred to.

Heterogeneous affinity urges heterogeneous particles towards each other, and keeps them at insensible distances, and of course is the cause of the formation of new integrant particles composed of a certain number of heterogeneous particles.

Affinity, like sensible attraction, varies with the distance of the attracting bodies; but the rate at which it varies remains still unknown. The characteristic marks of affinity may be reduced to the three following.

1. It acts only at insensible distances, and of course affects only the particles of bodies.

2. Its force is always the same in the same particles, but it is different in different particles.

3. This difference is not affected by the mass. Thus, if A have a greater affinity for C than B has, the mass of B may be considerably increased while that of A remains unchanged, yet B is not capable of taking a part of C from A.* Let us now take a particular view of gases, liquids, and solids, that we may ascertain in what way they unite, and how far their combinations are influenced by the state of the bodies themselves.

CHAP. I.

Of Gases.

Of Gases.

GASES are elastic fluids, which yield to the smallest impression, and have their parts easily moved. Their elasticity varies with the pressure, and hence it follows that their particles mutually repel inversely as the distances of their centres from each other. The gaseous bodies at present known (including some vapours) amount to 22. The following Table exhibits their names and their specific gravity.

Gases.	Specific Gravity.
Air	1.000
Chloric gas	2.713
Nitric acid	2.427
Sulphurous acid	2.097

---

* This is the law for many years received by chemists as an axiom, and illustrated by Bergman at great length. It was lately called in question by Berthollet. But the experiments on which his opinion was founded have not stood the test of repetition.

Gases.	Specific Gravity.
Vapour of ether	2.250
Vapour of alcohol	2.100
Muriatic acid	1.278
Fluoric acid	——
Nitrous oxide	1.603
Carbonic acid	1.518
Sulphureted hydrogen	1.147
Oxygen	1.093
Nitrous gas	1.038
Azote	0.969
Carbonic oxide	0.956
Olefiant gas	0.974
Steam	0.700
Ammonia	0.600
Carbureted hydrogen	0.555
Arsenical hydrogen	0.529
Phosphureted hydrogen	0.852
Hydrogen	0.074

The gases usually contain water. This liquid, in most of them, is in the state of vapour, and intimately united. It may be partly separated by cold or by substances which have a strong affinity for water, as sulphuric acid, dry muriate of lime, and the dry fixed alkalies. From the experiments of Saussure we learn, that a hundred cubic inches of air saturated with moisture at the temperature of 57° contain 0.35 of a grain troy of moisture.

When gaseous bodies are brought into contact with each other, they mix equably, how much soever they differ in specific gravity; and when once mixed, they never after separate. By this mixture, neither the bulk nor the specific gravity of the gaseous bodies is altered. This mutual mixture seems to be analogous to what happens when liquids are mixed together, and seems explicable in the same way. It seems to be owing to a weak attraction which exists between the particles of all gaseous bodies. Mr Dalton affirms, that it is owing entirely to the difference between the size of the particles of different gases.

Several gases have the property of uniting intimately with each other, and of forming new products possessing peculiar properties. The following Table exhibits a view of those that unite upon simple mixture with the products which they form.

		Products.
Oxygen with	nitrous gas	Nitrous acid. Nitric acid.
Ammonia with	vapour	Liquid ammonia.
	muriatic acid	Muriate of ammonia.
	fluoric acid	Fluate of ammonia.
	carbonic acid	Carbonate of ammonia.
	sulphurous acid	Sulphite of ammonia.
	sulphureted hydrogen	Hydrosulphuret of ammonia.

The following are the gases which combine only in particular circumstances with the products which they form.

		Products.
Oxygen with	hydrogen	Water.
	carbonic oxide	Carbonic acid.
	azote	Nitric acid.
	sulphurous acid	Sulphuric acid.
	nitrous oxide	Nitric acid.

The combination of the first two sets is produced by combustion, and may be accomplished either by a red heat, or by the electric spark. Oxygen and azote unite slowly by means of electric sparks, but without combustion. Little is known of the way in which the remaining sets combine.

From the experiments hitherto made, it follows, that when gaseous bodies unite, they unite either in equal bulks of each, or two or three parts by bulk of one, unite with one part by bulk with the other. The following Table exhibits a view of the proportions of the different constituents by bulk, of various compounds formed by the union of elastic fluids.

Compounds.	*Constituents by bulk.*	
Muriate of ammonia	100 ammoniacal	100 muriatic acid gas
Carbonate of ammonia	100 ditto	100 carbonic acid gas
Subcarb. of ammonia	100 ditto	50 ditto
Water	100 hydrogen gas	50 oxygen gas
Nitrous oxide	100 azotic gas	50 ditto
Nitrous gas	100 ditto	100 ditto
Nitric acid	100 ditto	200 ditto
Nitric acid	200 nitrous gas	100 ditto
Nitrous acid	300 ditto	100 ditto
Ammonia	100 azotic gas	300 hydrogen
Sulphuric acid	100 sulphurous acid	50 oxygen
Oxymuriatic acid	300 muriatic acid	100 ditto
Carbonic acid	100 carbonic oxide	50 ditto

Some gases, when mixed together, have the property of mutually decomposing each other. The following is a list of these gases.

Oxygen with	phosphureted hydrogen
Sulphureted hydrogen with	nitrous gas sulphurous acid

Many gases decompose each other by combustion, produced either by electric sparks, or by a red-hot body. The following are the principal of these gases.

Oxygen with	sulphureted hydrogen carbureted hydrogen olefiant gas vapour of ether ——— alcohol
Nitrous oxide with	hydrogen phosphureted hydrogen sulphureted hydrogen carbonic oxide carbureted hydrogen olefiant gas vapour of ether ——— alcohol
Nitrous gas with	hydrogen sulphurous acid
Hydrogen with	sulphurous acid carbonic acid
Vapour of water with	carbureted hydrogen olefiant gas

Water absorbs a certain portion of all the gases. Some of them are absorbed only in small quantity by that liquid, others in large quantity. The following Table exhibits the bulk of each gas absorbed by 100 parts of water freed from air by boiling, as determined by the experiments of Dr Henry and Mr Dalton.

Gases.	Absorption according to Henry.	Dalton.
Carbonic acid	108	100
Sulphureted hydrogen	106	100
Nitrous oxide	86	100
Olefiant gas	——	12.5
Nitrous gas	5	3.7
Oxygen gas	3.7	3.7
Phosphureted hydrogen	2.14	
Carbureted hydrogen	1.4	3.7
Azotic gas	1.53	1.56
Hydrogen	1.61	1.56
Carbonic oxide	2.01	1.56

Dr Henry's numbers are the result of experiment: Mr Dalton's of experiment modified a little by a happy generalization. He conceives that the degree of the absorption of each of the four sets into which the gases are divided by the horizontal lines in the preceding table may be represented as follows:

First set, Water absorbs its own bulk $= \frac{1}{1^3}$

Second set, ———————— $\frac{1}{8}$th its bulk $= \frac{1}{2^3}$

Third set, ———————— $\frac{1}{27}$ ——— $= \frac{1}{3^3}$

Fourth set, ———————— $\frac{1}{64}$ ——— $= \frac{1}{4^3}$

From this generalization, which holds at least very nearly, it follows that the density of the gases, after absorption, is either the same as before it, or at least some submultiple of it, and the distance between their particles is either the same as before, or twice, thrice, or four times as great.

Dr Henry has shown, that whatever be the density of the gas, the bulk of it absorbed is always the same. If carbonic acid gas be reduced by pressure to twice the usual density, water still continues to absorb its own bulk of it. Hence by increasing the pressure, water may be made to absorb any *quantity* of a gas whatever.

The gases still retain their elasticity after they have been absorbed by water, accordingly they make their escape if the water be placed under the exhausted receiver of an air pump.

The proportion of a gas absorbed by water, depends very much upon its purity. This water absorbs its own bulk of pure carbonic acid gas; but if the carbonic acid gas be mixed with common air, the proportion of it absorbed is much diminished. Water impregnated with a gas must be in contact with a portion of the very gas absorbed, otherwise that gas soon makes its escape altogether.

As the temperature increases, the absorbability of the gases by water diminishes, no doubt in consequence of the increased elasticity of the gases.

This absorption of the gases by water is probably the consequence of an affinity between them and that liquid. Hence the determinate proportion of each absorbed, and most of the other phenomena, admit of an easy explanation.

The alkaline and acid gases are very absorbable by water, and of course are acted on by a strong affinity. The following Table exhibits a view of the bulk of each gas absorbed by one measure of water.

Sulphurous acid, . .	33
Fluoric acid, ...	175 +
Muriatic acid, ...	516
Ammoniacal gas. . .	780

When a cubic inch of water is saturated with these gases, its bulk increases. The following Table exhibits the bulk of water when thus saturated, supposing the original bulk to have been 1.

Saturated with

Sulphurous acid,	1.040
Muriatic acid, . .	1.500
Ammoniacal, . . .	1.666

Thus the water undergoes an expansion, so that the density of the gases absorbed is not in reality so great as it appears to be. The following Table exhibits the real densities of these gases in the water.

Sulphurous, ... 31.7 $= 3^3$ nearly.
Muriatic, ... 344.0 $= 7^3$
Ammonia, ... 468.0 $= 8^3$

That these gaseous bodies combine chemically with water, cannot be doubted.

The simple gases have the property of combining with different solid bodies, and of forming compounds sometimes gaseous, sometimes liquid, and sometimes solid. Oxygen combines with two dozes of carbon, forming carbonic acid, and carbonic oxide, both gases; the first a product of combustion, the second a combustible oxide. It combines with three doses of phosphorus, forming oxide of phosphorus, phosphorous acid, and phosphoric acid, all of which are solid bodies. It unites likewise with three doses of sulphur, and forms oxide of sulphur, sulphurous acid, and sulphuric acid; the first a solid, the second a gas, the third a liquid. It combines in various proportions with the metals, and all the metallic oxides are solids.

Hydrogen appears to combine in at least two proportions with each of the other simple combustibles. It unites also with several of the metals, but the proportions have not been ascertained.

Chap. II.

Of Liquids.

Of Liquids.

A liquid is a fluid, not sensibly elastic, the parts of which yield to the smallest impression, and move easily upon each other. All liquids have a certain cohesive force by which their particles are retained together, and this force is much greater in mercury than in water. The following Table exhibits a list of liquids, with their relative specific gravities.

Water	1.000
Ethers	0.632 to 0.900
Prussic acid	0.705
Petroleum	0.730 to 0.878
Volatile oils	0.792 to 1.094
Alcohol	0.796
Fixed oils	0.913 to 0.968
Supersulphureted hydrogen	——
Nitric acid	1.583
Sulphuric acid	1.885
Phosphuret of sulphur	——
Mercury	13.568

Most substances are rendered liquid by heat; but these are the only bodies that are permanently liquid in this country.

Some liquids may be mixed, and of course combine in any proportion whatever. In this respect they resemble the gases. The following is a list of these liquids:

Water with	alcohol. nitric acid. sulphuric acid.
Alcohol with . . .	ether.
Sulphuric acid with	nitric acid.
Fixed oils with . .	petroleum. volatile oils. fixed oils.
Volatile oils with .	petroleum. volatile oils.

These liquids, when once mixed, form a homogeneous compound, and do not afterwards separate again. The union is attended with the evolution of heat, and with a certain degree of condensation, for the specific gravity is always greater than the mean.

The following Table exhibits a list of those liquids that unite with each other only in certain proportions.

Water with	ether. volatile oils.
Alcohol with . . .	volatile oils. petroleum. phosphuret of sulphur.
Ether with	volatile oils. petroleum.
Volatile oils with .	petroleum.

The following Table exhibits a list of the most remarkable liquids that do not sensibly combine:

Water with	petroleum. fixed oils. supersulphureted hydrogen.
Fixed oils with . .	ether.
Mercury with . . .	water. alcohol. ether. volatile oils. petroleum.

No doubt the action of liquids on each other depends upon their affinity. The first class have the greatest affinity for each other; that of the second is greater, and that of the third is less than the cohesion of the particles of each.

Water has the property of combining with a very great number of solid bodies. It combines with them in two ways. In the first way, the solid retains its solidity, while the water loses its liquid form. Such combinations are called *hydrates*. In this way water combines with sulphur, metallic oxides, earths, alkalies, many acids, all salts, hydrosulphurets, and many animal and vegetable substances. In the second way, the water dissolves the solid, and the whole becomes liquid. In this way it acts upon many acids, alkalies, earths, salts, and vegetable substances.

These combinations are all chemical, and the hydrates appear to be the most intimate. Their specific gravity is always greater than the mean, while the specific gravity of saline solutions is usually less than the mean.

The action of the other liquids on solids has been hitherto but imperfectly investigated.

CHAP. III.

Of Solids.

Of Solids.

SOLIDS are bodies composed of particles that cohere together, and cannot be moved among themselves without the exertion of a force sufficient to destroy the cohesion of the body. They are very numerous, and their specific gravity varies more than that of gases or liquids. The following Table exhibits the specific gravity of the most remarkable solids:

	Sp. Gravity.
Charcoals	0.223 to 1.526
Vegetable bodies	0.240 to 1.354
Salts	0.273 to 7.176
Earths	0.346 to 4.842
Solid acids	0.667 to 3.391
Earthy compounds . . .	0.680 to 4.815
Bitumens and solid oils . .	0.892 to 1.357
Fixed alkalies	1.336 to 1.708
Phosphorus	1.770
Carburets of iron . . .	1.987 to 7.840
Sulphur	1.990
Glass	2.732 to 3.329
Carbon	3.518 to 3.531
Metallic sulphurets . . .	3.225 to 10.000
Metals and alloys and oxides	0.600 to 23.00

The following solids combine with each other in any proportion whatever:

Sulphur with phosphorus.
Carbon with iron?
Metals with most metals.
Protoxide of antimony with sulphuret of antimony.
Earths with earths.
Earths with some metallic oxides.
Some earths with fixed alkalies.
Fixed alkalies with solid oils.
Solid oils with each other and with bitumen.

All these combinations are produced by means of heat; unless they be brought into fusion, or at least one of them, they do not combine.

The following Table exhibits the principal solids, which have been observed to unite only in determinate proportions:

Sulphur with	metals. some metallic oxides. earths. fixed alkalies?
Phosphorus with . .	carbon. metals. some earths.
Acids with . . .	alkalies. earths. metallic oxides.

These combinations are more intimate than the preceding, they have been more accurately examined, and are better known. They never take place, unless one of the bodies at least be brought first into a liquid state, either by means of heat, or by solution in water.

The salts are the most important of these combinations, and a vast number of experiments have been made, in order to ascertain the proportions in which their constituents combine. The following Table exhibits the general result of these experiments. The numbers represent the weight of the different acids and bases which neutralize each other respectively.

Acids.		Bases.	
Sulphurous . .	54	Barytes . .	72.8
Oxalic . . .	39.5	Strontian . .	46
Nitric . . .	33.3	Potash . .	42.11
Sulphuric . . .	37.5	Soda . . .	29.75
Phosphoric . .	23	Lime . . .	27.2
Muriatic . . .	18	Magnesia . .	17.76
Carbonic . . .	20.5	Ammonia . .	9
Phosphorous . .	32		

Suppose we wish to form sulphate of barytes—from the above Table, it appears that we must unite together 37.5 parts by weight of sulphuric acid, and 72.8 parts of barytes.

From various experiments hitherto made, it appears that the supersalts contain twice as much acid, and the subsalts twice as much base, as the neutral salts. Suppose that a given quantity of sulphate of potash is composed of 100 potash, united with x of sulphuric acid, then supersulphate of potash is composed of 100 potash, united with $2x$ sulphuric acid. The triple salts appear to consist of two different salts united together. Thus alum may be considered as a compound of *sulphate of potash* and *sulphate of alumina*.

According to the old doctrine of affinity delivered by Bergman, all bodies capable of combining have an affinity for each other. This affinity is a constant force, which may be represented by numbers. Affinity is *elective*; that is to say, if a has a stronger affinity for m than b has, and if m be combined with b, forming a compound which we may represent by mb; a, upon being mixed with this compound, has the property of separating b completely from m, and taking its place, so as to form a compound ma, while b is entirely disengaged. This doctrine has been lately called in question by Berthollet. According to Berthollet, affinity is not elective, and never occasions decomposition, but only combination. The decompositions which take place are owing to other causes, such as insolubility, elasticity, &c. though this new opinion (if accurate) renders Bergman's tables of decomposition of little comparative value; yet, as it is, seems inconsistent with facts, and as his tables are in some cases useful, and are often referred to, it has been thought worth while to subjoin them here.

Table of Chemical Decompositions.

PART II.

CHEMICAL EXAMINATION OF NATURE.

Chemical Examination of Nature.

Having in the First Part of this article given a sufficient detail of the principles of Chemistry, and described the substances which are usually employed as instruments of investigation, it remains for us now to take a view of the different substances, as they exist in nature, constituting the material world, that we may ascertain how far the science of Chemistry will serve towards explaining their nature, and accounting for the various changes which they produce on each other. Now the different substances of which the material world, as far as we have access to it, is composed, may be arranged under the five following heads:

1. The Atmosphere.
2. Waters.
3. Minerals.
4. Vegetables.
5. Animals.

We shall take a view of each of these in succession.

BOOK I.

OF THE ATMOSPHERE.

Of the atmosphere.

The atmosphere is that invisible fluid which surrounds the earth to an indeterminate height, and which got its name from the Greeks, in consequence of the vapours that are continually floating in it. Two things respecting it claim our attention; 1. Its composition. 2. The changes which take place in it.

Chap. I.

Of the Composition of the Atmosphere.

Composition of the atmosphere.

For all the knowledge of the atmosphere which we possess, we are indebted to the moderns. The ancients made no progress in the investigation. Its weight was determined by Galileo, and his disciple Torricelli; its density, elasticity, and most of its mechanical properties, by Boyle; its relation to light and sound, by Hooke, Newton, and Derham: but for our knowledge of its composition, we are indebted to the labours of the chemists of the last century. Hales began the subject. Dr Black made an additional step. Dr Priestley discovered the substances of which it is composed. But Scheele and Lavoisier were the philosophers who first placed the subject in its true light; and the matter was in some measure completed by Mr Cavendish. The atmosphere consists always of the three following distinct parts. 1. Air. 2. Water. 3. Carbonic acid.

Sect. I. *Of Air.*

Air.

The word air is often used to denote the atmosphere in general; but in strict language it is applied to an elastic fluid, which constitutes by far the greatest portion of the atmosphere, and which is distinguished from the moisture and carbonic acid with which it is always mixed.

Its properties.

Air is an invisible elastic fluid. Its specific gravity is always reckoned 1.000; and its weight is such, that, at the temperature of 60°, and when the barometer stands at 30 inches, 100 cubic inches of dry air weigh 30.5 grains troy.

Its density always increases with the pressure, so that its bulk is always inversely as the pressure. Air itself, though it has the property of refracting light, is invisible. The blue colour of the sky is owing to the vapours with which the air is always mixed; and it depends upon the quantity of these vapours.

Air was determined by Scheele to be a mixture of oxygen gas and azotic gas; and this conclusion was confirmed by the experiments of Lavoisier, and of all subsequent chemists. Scheele determined the proportion of these two gases to be 27 by bulk of oxygen gas, and 73 of azotic gas. In these proportions M. Lavoisier acquiesced. Their method was to absorb the oxygen from a given bulk of atmospheric air, and to determine its quantity by the diminution of bulk. Mr Cavendish first demonstrated, that the proportion determined by Scheele and Lavoisier was inaccurate. He found air a mixture of 21 parts by bulk of oxygen gas, and 79 of azotic, very nearly. These proportions were confirmed by Berthollet, Davy, De Marti, and many other chemists, and are now universally acceded to.

Eudiometer.

The method of analysing atmospheric air is to abstract its oxygen, by means of some substance which has a strong affinity for it. The apparatus is usually called a *eudiometer*; because it was supposed at first that the proportion of oxygen in air is variable, and that the goodness of air depends upon the greatness of this proportion. And the name has been retained after this opinion has been given up.

First used by Dr Priestley.

The first eudiometer used was by Dr Priestley. It consisted in mixing 100 measures of air and 100 of nitrous gas in a tube. The goodness of the air was judged of by the greatness of the diminution. This method was improved by Fontana, and is usually distinguished by the name of the eudiometer of Fontana. Many attempts have been made to render it accurate; but it is in reality not much to be trusted, because the diminution of bulk varies with a variety of circumstances, which cannot easily be appreciated. It is greatest when a wide vessel is used, and least when the mixture is made in a narrow tube. According to Dalton, 21 measures of oxygen unite either with 36 measures of nitrous gas, or with $36 \times 2 = 72$ measures. The first proportion takes place in a narrow tube; the second in a wide vessel; in intermediate vessels the proportions are intermediate. Hence he uses a narrow tube. He lets up 100 measures of air, and then adds 50, or any greater number of measures of nitrous gas. The mixture takes place slowly, and the bulk gradually diminishes. In a few minutes, the diminution of bulk will have reached its maximum. Note it down, and multiply it by $\frac{7}{19} = 0.3684$. The product is the quantity of oxygen which the air examined contained. Suppose 100 measures of air to be examined, and the diminution of bulk to be 57;

Mr Dalton's eudiometer.

$$57 \times 0.3684 = 20.9988, \text{ or very nearly } 21.$$

This would indicate the oxygen in the air examined to be 21 measures. This method affords a tolerable approximation; but the error is generally greater than 1 per cent.

Mr Davy's eudiometer.

To avoid the ambiguity occasioned by the unequal diminution of bulk which takes place when air and nitrous gas are mixed, Mr Davy takes a strong solution of green sulphate of iron, makes it absorb a quantity of nitrous gas, and then agitates this liquid in the air to be examined. The whole oxygen is absorbed, and the diminution of bulk determines exactly how much oxygen the air contained. This method may be used, and is susceptible of great accuracy. The only objection to it, is the slowness with which the absorption of the oxygen takes place.

The liquid, made by boiling a mixture of lime and sulphur in a phial of water, which is yellow, may also be used with considerable precision. It was employed by Scheele, and in an improved form by De Morti. A stick of phosphorus in summer, may likewise be used with advantage. The residual gas ought to be agitated in water, to deprive it of a little phosphorus, which it usually holds in solution, and which may increase its bulk a little.

Volta's eudiometer.

But the best method of analysing air is the following, which was first put in practice by Volta, and is therefore called Volta's eudiometer. Mix equal bulks of air and hydrogen gas together, and pass an electric spark through the mixture. Combustion takes place. Note the diminution of bulk; one-third of that diminution is equal to the bulk of oxygen which the air examined contained.

Composition of air.

The result of all the trials hitherto made, gives us air a mixture of 21 measures of oxygen, and 79 of azote; or by weight, of

22.91 oxygen,
77.09 azote.
100.00

Sect. II. *Of Water.*

Water.

That water is always present in the atmosphere, is obvious from the clouds which constantly form in it, and from the rain and dew which are so frequently falling from it. Various instruments have been contrived to point out the quantity of water which the atmosphere contains. These instruments are called *hygrometers*. None of them are unexceptionable; but, upon the whole, the one contrived by Professor Leslie seems to be the best. From these instruments we learn, that the quantity of water in the atmosphere is exceedingly various. Sometimes very little can be detected, and sometimes the air is quite saturated with it.

Hygrometer.

From the experiments of Saussure, we learn, that a cubic foot of air, at the temperature of 66°, is capable of holding only about 8 grains troy, or $\frac{1}{81}$th its weight of water. The quantity increases with the temperature, and, according to Leslie, doubles for every additional 27° of temperature. Hence it is obvious, that the quantity of water in air depends, in some degree, on the temperature. At low temperatures, very little water can be present; but at high temperatures, air can contain a considerable quantity.

With respect to the state in which the water is contained in the air, there are two opinions which have divided philosophers. The first opinion is, that the water is dissolved by the air, and held in solution by it precisely as sugar or salt is by water. This opinion was started by Dr Hooke, explained at considerable length by Dr Halley, and fully discussed and supported by Leroy and Hamilton. The second opinion is, that the water is first converted into vapour, and that in that state it mixes with air precisely as one elastic fluid with another. This opinion, though with different modifications, was supported both by Saussure and Deluc, and has lately been maintained by Dalton, with arguments that appear decisive. When water evaporates or enters into air, it always produces cold, indicating a conversion into vapour. The same quantity of water evaporates, and continues in the state of vapour under an exhausted receiver, and in a receiver full of air. Vapour increases the bulk of air exactly in proportion to its quantity.

From the experiments of Dalton we learn, that in the torrid zone the quantity of vapour in the atmosphere varies from being able to support a column of mercury 0.6 inch in height, to being able to support a column 1 inch high. In Britain it seldom amounts to 0.6, but in summer is frequently at 0.5 inch. In winter it is often as low as 0.1 inch.

From this it appears, that the quantity of vapour in the atmosphere varies from $\frac{1}{50}$th to $\frac{1}{300}$th part of the atmosphere by weight. Mr Dalton supposes the medium quantity at once in the atmosphere to amount to about $\frac{1}{70}$th of its bulk.

Sect. III. *Of Carbonic Acid.*

Carbonic acid.

The existence of carbonic acid in the atmosphere became manifest, as soon as it had been determined by Dr Black, that alkalies owe their mild state to the presence of that gas. For it was known that a caustic alkali becomes gradually mild, when left exposed to the atmosphere. It has been found in air, upon the tops of mountains as well as in plains. Even air, brought by means of a balloon from the height of 4280 feet above the surface of the earth, was found to contain it. Hence we may conclude that it is universally diffused. The quantity of it is very small, and therefore determined with difficulty. At first it was conceived to amount to $\frac{1}{100}$th of the atmosphere, but it is certainly much less. Humboldt found it to vary from 0.005 to 0.01; but his method does not seem susceptible of precision. Dalton made it $\frac{1}{1400}$th of the air. Perhaps we shall not err far if we reckon it at a medium at $\frac{1}{1000}$th of the air. If we consider the numerous sources of this gas from the combustion of wood and coal and the breathing of animals, it must appear surprising that its bulk does not sensibly increase. This can only be accounted for by supposing, that nature has provided some means to decompose it as fast as it is formed.

For an account of the changes which take place in the atmosphere, see METEOROLOGY.

BOOK II. *Of Waters.* See the article WATERS.

BOOK III. *Of Minerals.* See the articles GEOGNOSY, MINERALOGY, ORYCTOGNOSY.

BOOK IV.

OF VEGETABLES.

Vegetables.

VEGETABLES are exceedingly numerous, nearly 40,000 species having been already described and arranged by botanists. It is the business of the chemist to analyse vegetables, to investigate the substances of which they are composed, the processes by which they are formed, and the changes to which they are subject after they have ceased to vegetate. We shall divide this Book into three Chapters. In the first, we shall give an account of the ingredients of plants; in the second, of the chemical phenomena of vegetation; and in the third, of the fermentations to which certain vegetable substances are liable, after they have ceased to vegetate.

CHAP. I.

Of the Ingredients of Plants.

Ingredients of plants.

THE substances hitherto found in the vegetable kingdom, all of them at least which have been examined with any degree of accuracy, may be reduced under four heads: I. Substances soluble in water, at least in some state or other, and which, in general, are solid and not remarkably combustible. II. Substances, either fluid, or which melt when heated, and burn like oil. They are all insoluble in water; but, in general, they dissolve in alcohol. III. Substances neither soluble in water, nor alcohol, nor ether, and which have a fibrous or woody texture. IV. Substances which belong to the mineral kingdom, which occur only in small quantity in vegetables, and may therefore be considered as extraneous or foreign. The following Table exhibits a view of the different vegetable substances hitherto discovered, arranged under their respective heads.

Table of vegetable substances.

I. 1. Acids.
2. Sugar.
3. Sarcocoll.
4. Asparagin.
5. Gum.
6. Mucus.
7. Jelly.
8. Ulmin.
9. Inulin.
10. Starch.
11. Indigo.
12. Gluten.
13. Albumen.
14. Fibrin.
15. Bitter principle.
16. Extractive.
17. Tannin.
18. Narcotic principle.

II. *Oleoform.*

1. Fixed oil.
2. Wax.
3. Volatile oil.
4. Camphor.
5. Bird-lime.
6. Resins.
7. Guaiacum.
8. Balsams.
9. Gum resins.
10. Caoutchouc.

III. *Fibrous.*

1. Cotton. 2. Suber. 3. Wood.

IV. *Extraneous.*

1. Alkalies. 2. Earths. 3. Metals.

The properties of these different substances form the subject of the following Sections.

SECT. I. *Of Acids.*

Acids found ready formed in vegetables.

The acids found ready formed in the vegetable kingdom are the following:—

1. Acetic.
2. Oxalic.
3. Tartaric.
4. Citric.
5. Malic.
6. Gallic.
7. Benzoic.
8. Prussic.
9. Phosphoric.

The sulphuric, nitric, and muriatic acids, are likewise to be found in vegetables combined with alkalies, but only in small quantities.

1. Acetic acid has been detected in the sap of different trees, in the acid juice of the *cicer parietinum,* and in the *sambucus nigra.*

2. Oxalic acid in the state of *superoxalate of potash,* exists in the leaves of the *oxalis acetosella, oxalis corniculata,* and different species of *rumex.* It exists uncombined in the juice of the *cicer parietinum.* In the state of *oxalate of lime* it is found in *rhubarb,* and in the roots and barks of a great variety of plants.

3. Tartaric acid is found in the pulp of the *tamarind,* in the juice of *grapes* and *mulberries*; likewise in the *rumex acetosa, rhus coriaria, rheum rhaponticum, agave americana, triticum repens, leontodon taraxacum.* In most of these plants it is in the state of supertartrate of potash.

4. Citric acid is found intermixed with other acids in the juice of *oranges* and *lemons,* and in the berries of *vaccinium oxycoccos, vaccinium vitis idæa, prunus padus, solanum dulcamara, rosa canina.* Mixed with other acids, it is common in many fruits. *Citrate of lime* is found in the onion.

5. Malic acid is very common in plants. It was found by Scheele, unmixed with any other acid, in the fruits of the following plants: the *apple, berberis vulgaris, prunus domestica, prunus spinosa, sambucus nigra, sorbus aucuparia.* Braconnot has found it in the leaves of most vegetables which he examined. Vauquelin found it in the state of *supermalate of lime* in the following plants; *sempervivum tectorum, sedum album, sedum acre, sedum telephium, arum maculatum,* and different species of *crassula* and *mesembrianthemum.* Mixed with citric acid, it constitutes the acid of the following fruits; *gooseberries, currants, bleaberries, cherries, strawberries, cloudberries, raspberries.* Sometimes, as in the tamarind, it is mixed with tartaric acid.

6. Gallic acid has been found in the bark of most

astringent tasted trees, as elm, oak, horse-chesnut, beech, willow, elder, plum, sycamore, birch, cherry-tree, mountain-ash, poplar, hazel, ash, sumach.

7. Benzoic acid has been found only in a few vegetable substances, to which the name of *balsam* has been given. The chief of these are *benzoin, balsam of Tolu, storax, dragon's blood.*

8. Prussic acid has been found in the leaves of the *lauro-cerasus,* in *peach blossoms,* in the flowers of the *sloe,* in the leaves of the bay-leaved *willow* (*salix pentandra*), and in most bitter tasted kernels.

9. Phosphoric acid is very common in plants, but only in small quantities, and it is usually combined with potash or lime. Phosphate of potash exists in barley and other species of corn, so does phosphate of lime. Both of these salts exist in the leaves of many trees.

Sect. II. *Of Sugar.*

Sugar.

Common sugar is obtained from the juice of the *arundo sacharifera* or *sugar cane,* a plant cultivated from time immemorial in India and China. It was unknown in Europe till after the conquests of Alexander the Great. The cultivation of the sugar cane was gradually introduced into Sicily and Spain, and, after the discovery of America, it was imported to the West Indian islands, where it has been cultivated to a great extent. Sugar has, in consequence, become a necessary of life among the modern nations of Europe.

How obtained.

The juice is extracted by passing the cane between iron rollers, and immediately run into a flat copper cauldron, where it is mixed with a little lime, and heated to the temperature of 140°. A thick viscid scum collects on the surface, which is left unbroken, and the clear liquid drawn from below and introduced into a large boiler. Here it is boiled briskly, the scum, as it forms, being constantly removed. From this first boiler it is passed into a second, from that to a third and fourth, in each of which the boiling is continued. When sufficiently concentrated, it is poured into a large wooden vessel called the *cooler,* where it crystallizes or *grains* as it cools. From the cooler it is taken and put into hogsheads, having a hole in the bottom, into which the stalk of a plantain leaf is thrust. Through these holes the *molasses* drain into a receiver. The sugar, thus cleared, is brought to this country under the name of *raw sugar.* It is refined by solution in water, clarified by bullock's blood, boiled down and poured into earthen cones, having a hole in the apex which is undermost. The base of the cone is covered with moist clay. From this the water slowly penetrates through the sugar, and carries off the impurities. In this state it is white, and is known by the name of *loaf sugar.*

From the experiments of Proust, it appears that sugar cane juice contains gluten, gum, extractive, a little malic acid, sulphate of lime, and two species of sugar. The object of the process is to remove all the substances, except the crystallizable sugar.

Its properties.

Sugar is a firm white substance, of an extremely sweet taste, but destitute of smell. It is but little altered by exposure to the atmosphere, though in damp air it is liable to become moist.

Cold water dissolves nearly its own weight of sugar, and boiling water dissolves any quantity whatever. The solution constitutes a thick, ropy, adhesive fluid, called syrup. When syrup is sufficiently concentrated, and kept in open vessels in a hot place, the sugar gradually crystallizes. The crystals are four or six-sided prisms, terminated by two-sided, and sometimes by three-sided summits.

The specific gravity of white sugar is 1.6065. It is not acted on by oxygen gas, by the simple combustibles, by azote, or by the metals. The alkaline earths combine with sugar, and form a compound which has a bitter and astringent taste. Sugar facilitates the solubility of lime and strontian in water; but barytes appears to act with more energy, and to occasion decomposition of sugar. The fixed alkalies combine with sugar, and form compounds similar to those formed by the alkaline earths.

The acids dissolve sugar, and the more powerful mineral acids decompose it. Nitric acid dissolves it with effervescence, converts one half of its carbon into carbonic acid, the residue assumes the form of water and oxalic acid. A quantity of malic acid is also evolved. 100 grains of sugar yield, by this treatment, 58 grains of oxalic acid. Sulphuric acid decomposes sugar, water and acetic acid are formed, and a great quantity of charcoal evolved.

Sugar dissolves in about 16 parts of boiling alcohol. If the solution be set aside, the sugar is gradually deposited in elegant crystals.

The hydrosulphurets, sulphurets, and phosphurets of alkalies and earths, seem to have the property of decomposing sugar, and of bringing it to a state not very different from that of gum.

When heat is applied to sugar, it melts, swells, becomes brownish black, emits air bubbles, and emits the smell of caromel. At a red heat it bursts into flames with a kind of explosion. When distilled, there comes over water; an acid liquid, called *pyromucous acid,* now known to be the acetic mixed with a little empyreumatic oil; an oil, and a bulky charcoal, remains in the retort. During the distillation a considerable quantity of carbonic acid and heavy inflammable air come over.

Composition according to Lavoisier.

From the experiments of Lavoisier, compared with some of our own, it appears that sugar is composed of

64	oxygen
28	carbon
8	hydrogen
100	

According to Gay-Lussac.

According to the experiments of Thenard and Gay-Lussac, the constituents of sugar are as follows:

Oxygen,	50.63
Carbon,	42.47
Hydrogen,	6.90
	100

Different kinds of sugar.

It appears from the recent researches of chemists, that there exist various species of sugar differing from each other in their properties. The most important of these are the following: Common sugar, liquid sugar, sugar of grapes, sugar of beet, manna.

Common sugar is the substance described in the preceding part of this Chapter. It is obtained from the sugar cane. The properties of the sugar of the maple are not known to differ from those of common sugar.

Liquid sugar was first pointed out by Proust. It exists in a variety of fruits and vegetable juices. It does not crystallize, and can only be exhibited in a liquid state. It is more soluble in alcohol than common sugar. It exists in the juice of the sugar-cane, and constitutes no inconsiderable portion of *molasses.*

Sugar was first extracted from grapes by the Duc de Bullion. They often yield, according to Proust, from

30 to 40 per cent. of sugar. He extracted it by saturating the acids contained in the juice of grapes with potash, boiling it down to one half, and setting it aside. Several of the salts subsided. The juice was then mixed with blood, heated, scummed, filtered, and boiled down to a syrup. Crystals of raw sugar gradually form, which may be purified by repeating the process. This sugar is white, but inferior in consistence to common sugar. It is not so sweet, and resembles sugar from honey. Like it, the sugar of grapes crystallizes in sphericles. It is less soluble than common sugar, and does not go so far in sweetening liquids.

Sugar was first extracted from the beet by Margraff. Many experiments were afterwards made upon the extraction, by Achard and other German philosophers, and attempts made to substitute the sugar of beet for common sugar, but it could not be obtained at a low enough price. It has a greater resemblance to common sugar than the sugar of grapes; but is distinguished by a certain nauseous bitter taste, owing perhaps to the presence of some foreign substance.

Manna is the produce of various trees, but is chiefly obtained from the *fraxinus ornus*, a species of *ash*, which grows abundantly in Sicily and Calabria. It partly exudes spontaneously during the summer months, and is partly obtained by incisions. The juice gradually concretes into a solid mass, or it is dried in the sun, or in stoves. Pure manna is very light, and appears to consist of a congeries of fine capillary crystals. Its taste is sweet, and it leaves a nauseous impression in the mouth. Hot alcohol dissolves it readily, and, on cooling, deposites about 5-8ths of the manna in the state of a fine light spongy crystalline mass, bearing some resemblance to camphor. This deposite may be considered as pure manna. It has an agreeable sweet taste, and instantly melts on the tongue, like snow in warm water. When dissolved in nitric acid, it yields oxalic acid. The saclactic appears also when the manna is impure. Manna does not undergo the vinous fermentation, and seems in consequence incapable of furnishing alcohol. Manna itself seems to be formed from uncrystallizable sugar by a species of fermentation.

The plants yielding sugar are very numerous. It seldom exudes spontaneously from vegetables, though this is sometimes the case.

SECT. III. *Of Sarcocoll.*

Sarcocoll.

This substance, which has hitherto been confounded with the gum resins, though its properties are very different, exudes spontaneously from the *penæa sarcocolla*, a shrub said by botanical writers to be indigenous in the north-eastern parts of Africa. It may be obtained pure by solution in alcohol, filtration, and evaporation.

Its properties.

Pure sarcocoll has a brown colour, is semitransparent, and very like gum in appearance. Its specific gravity is 1.2684.

It has a sweet taste, but leaves an impression of bitterness. It dissolves readily both in water and alcohol. The solution is yellow. It does not crystallize. When heated, it softens, but does not melt. It emits a slight smell of caromel. When strongly heated it blackens, and assumes the consistence of tar, emitting a heavy white smoke, having an acrid odour. Nitric acid dissolves it, but does not convert it into tannin. From these properties, sarcocoll appears to be intermediate between gum and sugar.

SECT. IV. *Of Asparagin.*

Asparagin

We give this name to a substance discovered in the juice of *asparagus*, by Vauquelin and Robiquet. The juice was evaporated to the consistence of a syrup, and set aside. Crystals of asparagin formed in it spontaneously.

Its properties.

These crystals are white and transparent, and have the figure of rhomboidal prisms. The greater angle of the rhomboidal base is 130°.

Asparagin is hard and brittle. Its taste is cool, and slightly nauseous, so as to occasion a secretion of saliva.

It dissolves readily in hot water, but in cold water only sparingly. Alcohol does not dissolve it.

The aqueous solution does not affect vegetable blues. Neither infusion of nutgalls, acetate of lead, oxalate of ammonia, muriate of barytes, nor hydrosulphuret of potash, occasion any change in it. When triturated with potash, no ammonia is disengaged. The potash seems to render it more soluble in water.

When heated it swells, and emits penetrating vapours, affecting the eyes and nose, like the smoke of wood. It leaves a large portion of insipid charcoal, which, when incinerated, gives scarcely a trace of residue.

Nitric acid dissolves it with the evolution of nitrous gas. The solution has a yellow colour, and a bitter taste, like that of animal substances in the same acid. Lime disengages from it a considerable quantity of ammonia.

SECT. V. *Of Gum.*

Gum.

There is a thick transparent tasteless fluid, which sometimes exudes from certain species of trees. It is very adhesive, and gradually hardens without losing its transparency, but easily softens again when moistened with water. This exudation is known by the name of gum. The gum most commonly used is that which exudes from different species of the *mimosa*, particularly the *nilotica*, and is known by the name of *gum arabic*.

How obtained.

Gum is usually obtained in small pieces like tears, moderately hard, and somewhat brittle while cold, so that it can be reduced by pounding to a fine powder. When pure it is colourless; but it has commonly a yellowish tinge, and it is not destitute of lustre. It has no smell. Its taste is insipid. Its specific gravity varies from 1.3161 to 1.4817.

Its properties.

It is not altered by exposure to the air, but the light of the sun makes it assume a white colour. Water dissolves it in large quantities. The solution, which is known by the name of *mucilage*, is thick and adhesive. It is often used as a paste, and to give stiffness and lustre to linen. When evaporated, the gum is obtained unaltered. Mucilage may be kept for years without undergoing putrefaction: at last, however, the odour of acetic acid becomes perceptible in it.

When gum is exposed to heat, it softens and swells, but does not melt; it emits air bubbles, blackens, and at last, when nearly reduced to charcoal, emits a low blue flame. A white ash remains, consisting chiefly of the carbonates of lime and potash.

Gum does not appear to be acted upon by oxygen gas, simple combustibles, azote, or the metals. The only metallic salts which occasion a precipitate when dropt into mucilage, are *nitrate of mercury*, and *acetate of lead*, both of which occasion a white precipitate. The superacetate of lead occasions no change. When oxymuriate of iron is poured into a strong mucilage, the whole is converted into a brown semitransparent jelly, which is not readily dissolved by water.

Neither the alkalies, alkaline earths, nor earthy salts, occasion any precipitate in mucilage; except silicated potash, which throws down a white flaky precipitate, even though very much diluted. The liquid remains transparent and colourless. Silicated potash is by far the most delicate test of gum that we have yet met with.

Liquid potash first converts gum into a substance not unlike curd, and then dissolves it. The solution is of a light amber colour, and transparent. When kept long, the gum falls again in the state of curd. Alcohol throws down the gum in white flakes, still soluble in water, but it retains the potash obstinately, and is much more friable than before. Lime water and ammonia likewise dissolve gum, and it may be afterwards separated little altered.

The vegetable acids dissolve gum without alteration, the strong acids decompose it. When thrown into sulphuric acid it blackens, and is decomposed. Charcoal is evolved, amounting to nearly one-third of the gum; some artificial tannin may be detected, and water and acetic acid are likewise formed. When gum is dissolved in strong muriatic acid, a brown solution is obtained, which becomes perfectly transparent when diluted with water, while at the same time some charry matter falls. If the solution be saturated with ammonia evaporated to dryness, and the residue digested in alcohol, the alcohol assumes a deep brown colour, and dissolves the whole except a little sal ammoniac. The gum now bears some resemblance to sugar in its properties, at least when heated it melts, and gives out a very strong smell of caromel.

If nitric acid be slightly heated upon gum till it has dissolved it, and till a little nitrous gas has exhaled, the solution on cooling deposites saclactic acid. Malic acid is formed at the same time, and if the heat be continued, the gum is at last changed into oxalic acid.

Gum is insoluble in alcohol. It is precipitated from water by alcohol. It is insoluble also in ether and in oils; but when triturated with a little oil, it renders the oil miscible with water.

Gum readily combines with sugar by mixing together the solutions of both in water, and evaporating to dryness. Alcohol digested on the residuum, dissolves most of the sugar; a matter remains which still has a sweetish taste, and resembles the substance of which the nests of wasps are formed.

When gum is distilled in a retort, the products are water impregnated with acetic acid and oil, or *pyromucous acid*, as it was formerly called, a little empyreumatic oil, carbonic acid gas, and heavy inflammable air. There remains in the retort charcoal containing lime and phosphate of lime. Gum yields also traces of iron when its ashes are examined, but no fixed alkali or sulphur can be detected.

Composition.

According to the analysis of Thenard and Gay-Lussac, gum is composed of

Oxygen	50.84
Carbon	42.23
Hydrogen	6.93
	100.00

Different kinds of gum.

The species of gum at present known are numerous, and a more rigid examination of the vegetable kingdom will doubtless discover a still greater number. The most remarkable are gum arabic, gum Senegal, gum tragacanth, and cherry tree gums.

Gum arabic exudes from the *mimosa nilotica*. It is the species described in the preceding part of this Chapter.

Gum Senegal.

Gum Senegal, brought from the island of that name, on the coast of Africa, often supplies the place of gum arabic in the shops. It is in larger masses than the arabic, and its colour is darker, but in other respects its properties are the same.

Gum tragacanth.

Gum tragacanth is the produce of the *astragalus tragacantha*, a thorny shrub which grows in Candia, and other islands of the Levant. It exudes about the end of June, from the stem and larger branches, and soon dries in the sun. It is in the state of whitish vermiform pieces, not nearly so transparent as gum arabic, and is exceedingly different from it in many of its properties. When put into water, it slowly imbibes a large quantity of the liquid, and forms a soft but not fluid mucilage. If the quantity of water be more than the gum can imbibe, the mucilage forms an irregular mass, which does not unite with the rest of the liquid. When tragacanth is treated with nitric acid, it yields abundance of saclactic acid, malic acid, and oxalic acid, but not the least trace of artificial tannin. When the mucilage of gum tragacanth is triturated in a mortar with water, it forms a homogeneous solution. This solution forms a precipitate with acetate and superacetate of lead and oxymuriate of tin. Nitrate of mercury throws down a slight precipitate; but neither oxysulphate of iron, nor silicated potash produce any effect. These properties show it to differ very materially from gum arabic in its properties.

Prunus avium.

The *prunus avium*, the common cherry and plum-trees, and the almond and apricot, likewise yield a gum which exudes in great abundance from natural or artificial openings in the stem. It is of a reddish brown colour, in large masses; at first much softer than gum arabic, but, by keeping, it becomes very hard. When put into water it gradually swells, and is converted into a semi-transparent reddish brown jelly. Part of it dissolves, but a part of it remains in the state of jelly, and refuses to dissolve even when boiled in water for some time. The gum dissolved is not precipitated by alcohol nor by silicated potash. Acetate of lead produces no immediate effect, but on standing the whole becomes opake, and a precipitate at last subsides. Stannane causes the liquid to gelatinize immediately. The superacetate of lead and the nitrate of mercury produce no effect. When treated with nitric acid it yields a portion of saclactic acid. These properties show a marked difference between cherry-tree gum and the other species.

SECT. VI. *Of Mucus.*

Mucus.

The substances to which we give the name of *mucus*, have been hitherto considered as varieties of gum; but, from the recent experiments of Dr Bostock, it appears that their properties differ so much from those of gum as to entitle them to a separate place as vegetable principles. They are very numerous, existing in the roots, leaves, and seeds of a great variety of plants. They scarcely ever separate spontaneously, but may be obtained artificially in a state of tolerable purity. Only a few of them have been examined. The rest are classed with these only from analogy.

Linseed yields mucus in a state of tolerable purity. When it is infused in ten times its weight of water, a fluid is obtained of the consistence of white of egg, which has the adhesive qualities of mucilage of gum arabic. When mixed with alcohol, the mucus is separated in white flocks, but the liquid does not become opake and milky like mucilage of gum arabic when mixed with alcohol. Acetate of lead throws down a copious dense precipitate. Superacetate of lead and oxymuriate of tin render the liquid opake, and also throw down a precipitate. Nitrate of mercury occasions a very slight precipitate, while muriate of gold, oxysulphate of iron, and silicated potash produce no sensible effect whatever. No change is produced by the infusion of nutgalls.

Quince seeds and the root of the hyacinth yield a mucus with the same properties, with some slight shades of difference, owing probably to the presence of foreign bodies mixed with it. The roots of the hyacinth, vernal squill, white lily, comfrey, and salop, contain so much mucus, that, when dried, they may be substituted for gum arabic. The leaves of the *malva sylvestris*, many of the fuci, and a good many of the stringy lichens, contain likewise abundance of mucus. In short, it is one of the most common of the vegetable principles. Probably there are few plants which do not yield some portion of it.

Sect. VII. *Of Jelly.*

Jelly.

How obtained.

If we press out the juice of black berries, currants, and many other fruits, and allow it to remain for some time in a state of rest, it coagulates into a tremulous soft substance, well known by the name of *jelly*. When it is washed with a small quantity of water, and then dried, we obtain it in a state approaching to purity.

Its properties.

It is nearly colourless, scarcely soluble in cold water, but very soluble in hot water, and, when the solution cools, it again coagulates into a jelly. When long boiled, it loses the property of gelatinizing, and becomes analogous to mucilage. When dried, it becomes transparent. When distilled, it yields the same products as gum. It seems very intimately connected with gum; but, as it has never been obtained in a state of complete purity, we are but imperfectly acquainted with its properties.

Sect. VIII. *Of Ulmin.*

Ulmin.

We give this name to a substance lately examined by Klaproth. It exuded spontaneously from the trunk of a species of elm, called by him the *ulmus nigra*, and was sent to Klaproth from Palermo in 1802.*

Its properties.

Externally, it has a good deal of resemblance to gum. It is solid, hard, of a black colour, and has considerable lustre. Its powder is brown. It dissolves readily in the mouth, and has an insipid taste.

Water dissolves it. The solution has a brown colour. Though very strong, it is not in the least adhesive or ropy, nor does it answer as a paste. It is insoluble in alcohol and ether, and is partially precipitated from water by alcohol.

When a few drops of nitric acid are added to the aqueous solution of ulmin, it becomes gelatinous, loses its brown colour, and a light brown substance precipitates. This precipitate is soluble in alcohol, and explodes when moderately heated. Hence, it is a compound of ulmin and nitric acid. Muriatic and sulphuric acids produce likewise yellowish brown precipitates, which are insoluble in water. Ulmin is likewise precipitated by sulphate of iron, muriate of tin, and acetate of lead, but not by nitrate of silver, nor solution of glue.

Ulmin when burnt emits little smoke or flame; it leaves a spongy but firm charcoal, which yields, when concentrated, a little carbonate of potash.

Sect. IX. *Of Inulin.*

Inulin.

We give this name to a substance discovered by Rose in the root of the *inula helenium*, or *elecampane*. When the root of this vegetable was boiled in water, the decoction, after standing some hours, deposits the *inulin* in the form of a white powder like starch.

Its properties.

It is insoluble in cold water. By trituration the inulin is uniformly diffused, and gives the liquid an opal appearance, but it soon falls down in the state of a white powder, leaving the liquid quite transparent.

It dissolves readily in hot water. One part of inulin in four parts of boiling water, formed a solution which passed readily through the filter. After some hours, the greater part of the inulin precipitates from the water in the form of a white powder.

When the aqueous solution of inulin is mixed with an equal bulk of alcohol, no change takes place for some time; but the inulin soon separates and falls to the bottom in the state of a bulky white powder. A solution of gum arabic, when treated in this manner, remains milky for days without any precipitate falling.

When thrown upon burning coals, it melts as readily as sugar, and emits a thick white smoke, not unpleasantly pungent, and similar in odour to that of burning sugar. The residue, which is but small, sinks into the coal. Starch emits a similar smoke, but leaves a more bulky residue. When exposed to a red heat, inulin burns with a vivid flame, and leaves a very small coaly residue.

When distilled, inulin yields a brown acid liquid, having the smell of pyromucous acid, but not a trace of oil.

When inulin is treated with nitric acid, it yields malic and oxalic acids, or acetic acid if too much nitric acid be employed. But no saclactic acid is formed as happens with the gums, neither is any of the waxy matter separated, which makes its appearance when starch is digested in nitric acid.

Sect. X. *Of Starch.*

Starch.

How obtained.

If a quantity of wheat flour be formed into a paste, and then held under a very small stream of water, kneading continually till the water runs off from it colourless, the flour, by this process, is divided into two distinct constituents. A tough substance of a dirty white colour, called *gluten*, remains in the hand; the water is at first milky, but soon deposits a white powder, which is known by the name of *starch*.

The starch obtained by this process is not quite free from gluten. Hence it is not very white, and has not that crystallized appearance which distinguishes the starch of commerce. Manufacturers employ a more economical and more efficacious process. Wheat is steeped in water till it gives out a milky juice when squeezed, it is then put into coarse linen sacks, which are subjected to pressure in a vessel of water till the whole starchy matter is separated. The sack and its contents are then removed. The water containing the starch gradually ferments. Vinegar and alcohol are formed in it, partly, no doubt, at the expence of the starch. The vinegar thus formed dissolves all the impurities, and leaves nothing behind but the starch. It is poured off, and the starch being

---

[*] There is no doubt that ulmin exudes from the common elm, nor that it is one of the substances originally described by Vauquelin as proceeding from the ulcers to which that tree is subject.

edulcorated with water, is dried with a moderate heat. During the drying, it usually splits into columnar masses, which have a considerable degree of regularity.

Starch was well known to the ancients. According to Pliny, the method of manufacturing it was discovered by the inhabitants of Chios.

Its properties.

Starch has a fine white colour, and is usually concreted in four-sided prisms. It has scarcely any smell, and very little taste. When kept dry, it continues for a long time uninjured, though exposed to the air.

It does not dissolve in cold water, but very soon falls to powder, and forms a kind of emulsion. It dissolves in boiling water, and forms a kind of jelly, which may be diffused through boiling water; but when the mixture is allowed to stand a sufficient time, the starch slowly precipitates to the bottom. The subsidence takes place even when 90 parts of water are employed to dissolve one of starch; but, in that case, at least a month elapses before the starch begins to precipitate. The solution is glutinous in proportion to the quantity of starch. Linen dipt into it and suddenly dried, acquires a considerable degree of stiffness. When the solution is evaporated to dryness, a brittle opake mass is obtained, differing in appearance from common starch, but exhibiting nearly the same properties with re-agents. Hence the apparent difference is probably owing to a portion of water remaining united to the boiled starch. When the solution of starch is left exposed to damp air, it soon loses its consistency, acquires an acid taste, and becomes mouldy on the surface.

Starch does not dissolve, nor even fall to powder in alcohol. Neither does it dissolve in ether.

Neither oxygen gas nor the simple combustibles have any marked action on starch. The metals and their oxides have little affinity for it. Acetate of lead throws it down from water, but the superacetate has no effect upon it. According to Dr Bostock, it is precipitated also by oxymuriate of tin; but in the trials made by the writer of this article, he obtained no precipitate with that salt in a decoction containing one-ninetieth of its weight of starch. No other metallic salt tried produced a precipitate in this decoction.

Neither lime nor strontian water precipitate the decoction of starch; but barytes water throws down a copious white flaky precipitate. It is dissolved by muriatic acid, but appears again on standing, unless a considerable excess of acid be added. Neither muriate of barytes nor silicated potash occasion any precipitate in the decoction of starch.

When starch is triturated in a hot infusion of nutgalls, a complete solution is effected. This solution is transparent, and rather lighter coloured than the infusion of nutgalls employed. When this solution cools, it becomes opake, and a copious curdy precipitate falls. A heat of 120° re-dissolves this precipitate, and renders the solution transparent, but it is deposited again as the liquid cools. This property is characteristic of starch. The infusion of nutgalls throws it down from every solution, but the precipitate is re-dissolved by heating the liquid to 120°. The precipitate is a compound of tannin and starch, and is least soluble when composed of about three parts starch, and two parts tannin. It has a brownish yellow colour, is semi-transparent, has an astringent taste, and feels glutinous between the teeth like gum.

When potash is triturated with starch, and a little water added, the whole assumes, on standing, the appearance of a semi transparent jelly. On adding water, an opal coloured solution is obtained, from which the starch is readily thrown down by an acid. When muriatic acid is employed, a peculiar aromatic odour is perceived. The decoction of starch is neither altered by potash, carbonate of potash, nor ammonia.

When starch is thrown into any of the mineral acids, at first no apparent change is visible; but, if an attempt is made to reduce the larger pieces, while in acids, to powder, they resist it, and feel exceedingly tough and adhesive. Sulphuric acid dissolves it slowly, and at the same time a smell of sulphuric acid is emitted, and such a quantity of charcoal evolved, that the vessel may be inverted without spilling any of the mixture. Diluted sulphuric acid dissolves starch when assisted by heat, and the starch may be again precipitated by means of alcohol.

Diluted nitric acid slowly dissolves starch; the acid acquires a green colour, and a small portion of white matter swims on the surface, on which the acid does not act. Alcohol throws down the starch from this solution. Concentrated nitric acid dissolves starch pretty rapidly, assuming a green colour, and emitting nitrous gas. The solution is never complete, nor do any crystals of oxalic acid appear unless heat be applied. In this respect starch differs from sugar, which yields oxalic acid even at the temperature of the atmosphere. When heat is applied to the solution of starch in nitric acid, both oxalic and malic acids are formed, but the undissolved substance still remains. When separated by filtration, and afterwards edulcorated, this substance has the appearance of a thick oil not unlike tallow; but it dissolves readily in alcohol. When distilled it yields acetic acid and an oil, having the smell and consistence of tallow.

Strong muriatic acid dissolves starch slowly and without effervescence. When the starch does not exceed one-twentieth of the acid, the solution is colourless and transparent; but if we continue to add starch, a brown colour appears, and the acid loses a portion of its fluidity. Its peculiar smell is destroyed, and replaced by the odour which may be perceived in corn mills. Acetic acid does not dissolve starch. The action of the other acids has not been tried.

Alcohol separates starch in part from its decoction. A solution of potash in alcohol occasions a copious white precipitate, which is re-dissolved on adding a sufficient quantity of water. A solution of sulphuret of potash in alcohol occasions a flaky precipitate in the decoction of starch. This precipitate has sometimes an orange colour.

When starch is thrown upon a hot iron, it melts, blackens, froths, swells, and burns with a bright flame like sugar, emitting at the same time a great deal of smoke; but it does not explode, nor has it the caromel smell which distinguishes burning sugar. When distilled, it yields water, impregnated with an acid supposed to be the pyromucous, a little empyreumatic oil, and a great deal of carbonic acid and heavy inflammable air. The charcoal which it leaves burns easily when kindled in the open air, and leaves very little ashes. According to the experiments of Thenard and Gay-Lussac, it is composed of

Composition.

Oxygen	49.68
Carbon	43.55
Hydrogen	6.77
	100

Starch is contained in a great variety of vegetable substances; most commonly in their seeds or bulbous roots, but sometimes also in other parts. All the different species of corn contain a great proportion of it. There are obviously different varieties of starch, possessing distinct properties. But hitherto these varieties have not been examined with such attention as to enable us to give a detailed description of each.

SECT. XI. *Of Indigo.*

Indigo.

This valuable pigment, one of the capital manufactures of America, is obtained from the leaves of different species of plants: the *indigofera argentea* or *wild indigo*, the *indigofera disperma* or *Guatimala indigo*, and the *indigofera tinctoria* or *French indigo*, which yields the greatest quantity of indigo, and is therefore preferred by the planter, though its quality is said to be inferior to that of the indigo obtained from the two first species. In the West Indies the seeds are sown in March, in trenches about a foot asunder, and the plant comes into blossom, and is fit for cutting down in May. But in South America, six months elapse before it can be cut. In the West Indies, four cuttings are often obtained from the same plant in the course of a year; but in America, never more than two, and often only one. The produce constantly diminishes after the first cutting, so that it is necessary to renew the plants for seed every year.

How obtained.

The plants are cut down with sickles, and laid in strata in the *steeper* till it is about three parts full. This is a large cistern of wood or mason work about 16 feet square. Here they are pressed down with planks, and loaded to prevent them from swimming, and covered with water to the height of four or five inches. Here they ferment, and the utmost attention is required to the process. If they be allowed to remain too long, the pigment is spoiled; and if the water be drawn off too soon, much of the indigo is lost. The temperature of 80° is said to answer best. The water acquires a green colour, a smell resembling that of ammonia is exhaled, and bubbles of carbonic acid are emitted. When the fermentation has continued long enough, the liquor is let out into a second cistern placed lower than the first; this cistern is called the *battery*, and is commonly above 12 feet square, and four and a half deep. Here it is agitated for 15 or 20 minutes, by means of levers driven by machinery, till the flocculi beginning to separate give it a curdled appearance. A quantity of lime-water is now poured in, and the blue flocculi are allowed to subside. The water is then drawn off, and the pigment put to be drained in small linen bags, after which it is put into little square boxes, and allowed to dry in the shade.

Chevreul has shown, that the indigo exists in the plant chiefly in the state of a white matter, which becomes blue when it combines with oxygen. Indigo may be obtained also from other plants, the *nerium tinctorium*, for example, and the *isatis tinctoria*, or *woad*, a plant common enough in Britain. But the quantity obtained from this plant does not exceed one-tenth of what may be procured from the *indigofera*.

Its properties.

Indigo is a fine light friable substance of a deep blue colour. Its texture is very compact, and the shade of its surface varies according to the manner in which it has been prepared. The principal tints are copper, violet, and blue. The lightest indigo is the best; but it is always mixed with foreign substances, scarcely one half even of the best indigo of commerce consisting of the pure pigment. The following substances were extracted by Chevreul from 100 parts of Guatimala indigo:

Composition of Guatimala indigo.

Ammonia, a trace	
Disoxygenized indigo . . .	12
Green matter	30
Bitter matter, a trace	
Red matter	6
Carbonate of lime	2
Oxide of iron and alumina . .	2
Silica	3
Pure indigo	45
	100

Pure indigo has neither taste nor smell. It is insoluble in water in its usual state, but disoxygenized indigo is soluble in that liquid, as are likewise some of the foreign bodies with which indigo is usually mixed. When heated, indigo sublimes in a purple smoke, and may be obtained unaltered crystallized in needles. This purple smoke is characteristic of indigo.

Neither oxygen nor the simple combustibles have any action on common indigo; but disoxygenised indigo readily combines with oxygen, and may be separated again from it without decomposition. In this respect it differs from almost all other vegetable substances, and approaches the properties of the simple combustibles and metals.

The fixed alkaline solutions have no effect upon indigo, except it be newly precipitated from a state of solution. In that case they dissolve it with facility. The solution has at first a green colour, which gradually disappears, and the natural colour of the indigo cannot be again restored. Hence we see, that the alkalies when concentrated decompose indigo. Pure liquid ammonia acts in the same way. Even carbonate of ammonia dissolves precipitated indigo, and destroys its colour.

Lime-water has scarcely any effect upon indigo in its usual state, but it dissolves precipitated indigo. The solution is at first green, but it becomes gradually yellow.

When diluted sulphuric acid is digested over indigo, it produces no effect except that of dissolving the impurities; but concentrated sulphuric acid dissolves it readily. One part of indigo, when mixed with eight parts of sulphuric acid, evolves heat, and is dissolved in 24 hours. The solution of indigo is well known in this country by the name of *liquid blue*. Bancroft calls it *sulphate of indigo*. While concentrated, it is opake and black; but when diluted, it assumes a fine deep blue colour, and its intensity is such, that a single drop of the concentrated sulphate is sufficient to give a blue colour to many pounds of water. Bergman ascertained the effect of different reagents on this solution with great precision. His experiments threw light not only on the properties of indigo, but upon the phenomena that take place when it is used as a dye-stuff.

From his experiments, it is obvious that all those substances which have a very strong affinity for oxygen give a green colour to indigo, and at last destroy it. Hence it is extremely probable, that indigo becomes green by giving out oxygen. Of course it owes its blue colour to that principle. This theory was first suggested by Mr Hauseman, and still farther confirmed by Berthollet. Now it is only when green that it is in a state capable of being held in solution by lime, alkalies, &c. in which state it is applied as a dye to cloth. The cloth, when dipt into the vat containing it thus dissolved, combines with it, and the blue colour is restored by exposure to the atmosphere. It may be restored equally by plunging the cloth into oxymuriatic acid. Hence the restoration cannot but be ascribed to oxygen. Hence then the reason that sulphurous acid, the vegetable acids, sulphate of iron, give sulphate of indigo a green colour.

From these experiments, we see also that the colour of indigo is destroyed by the addition of those substances which part with oxygen very readily, as the black oxide of manganese. In that case the indigo is destroyed, for its colour cannot be again restored. When the sulphate of indigo is poured into boiling water, it affords a green-coloured solution; but with cold water a deep blue solution. What is called smoking sulphuric acid dissolves indigo much more readily than the pure acid, and evolves much more heat during the solution. Bucholz has shown, that by boiling sulphur in pure sulphuric acid, it acquires the property of dissolving indigo as readily as the smoking acid.

Nitric acid attacks indigo with great violence; with the evolution of abundance of heat and nitrous gas. When of the specific gravity 1.52, it even sets fire to indigo. When the acid is diluted, the action is still violent, unless the proportion of water be considerable. Mr Hatchett poured upon 100 grains of indigo an ounce of nitric acid, diluted with an equal quantity of water. The action was so rapid, that he found it necessary to add another ounce of water. When the effervescence had nearly subsided, the liquid was placed on a sand bath for some days, and evaporated to dryness. Water poured upon the residuum dissolved a considerable portion of it, and formed a beautiful deep yellow solution of an intense bitter taste. This solution contains only a very small portion of oxalic acid; but with a solution of isinglass it forms a copious yellow insoluble precipitate, and of course contains a portion of artificial tannin. With ammonia crystals precipitate, consisting of *bitter principle* combined with ammonia.

When four parts of nitric acid are boiled upon one part of indigo, the pigment soon loses its colour, and is dissolved. The solution becomes yellow, and a thin layer of a resinous matter appears on the surface. If the process be now stopt, the resinous matter becomes thin by cooling. If this matter be removed, and the solution evaporated to the consistence of honey, redissolved in hot water and filtered, potash throws down yellow spicular crystals, consisting of *bitter principle* combined with potash. These crystals have the curious property of detonating with a purple light, when wrapt up in paper, and struck with a hammer; the resin, by treating it with fresh nitric acid, may be converted into the same bitter principle. If the process be stopt sooner than the point mentioned above, yellow crystals are obtained, which are more soluble in water, and which sublime in white needles, having all the properties of benzoic acid.

Muriatic acid does not act upon indigo in its common state, but it readily dissolves indigo precipitated from the sulphate, and forms a blue-coloured solution. The same phenomena are exhibited by the phosphoric, acetic, tartaric acids, and probably by all except the acid supporters.

Chlorine destroys the colour of indigo as readily as nitric acid.

Alcohol dissolves a small portion of indigo, but it gradually precipitates again unless *red matter* be present, in which case the solution is permanent.

Indigo is not acted upon by ether or oils, at least if the experiments of Bergman be accurate.

When indigo is mixed with bran, woad, and other similar substances which readily undergo fermentation, it assumes a green colour during the fermentation, and is then easily dissolved by lime or potash. It is by this process that it is usually rendered proper for dyeing.

SECT. XII. *Of Gluten.*

Gluten.

If wheat-flour be kneaded into paste with a little water, it forms a tenacious, elastic, soft, ductile mass. This is to be washed cautiously, by kneading it under a small jet of water, till the water no longer carries off any thing, but runs off colourless; what remains behind is called *gluten*. It was discovered by Beccaria, an Italian philosopher, to whom we are indebted for the first analysis of wheat-flour.

How obtained.

Its properties.

Gluten, when thus obtained, is of a grey colour, exceedingly tenacious, ductile, and elastic, and may be extended to twenty times its original length. When very thin, it is of a whitish colour, and has a good deal of resemblance to animal tendon or membrane. Its smell is peculiar. It has scarce any taste, and does not lose its tenacity in the mouth.

When exposed to the air, it gradually dries; and when completely dry, it is pretty hard, brittle, slightly transparent, of a dark brown colour, and has some resemblance to *glue*.

Fresh gluten imbibes water, and retains a certain quantity of it with great obstinacy. To this water it owes its elasticity and tenacity. When boiled in water it loses both these properties.

When fresh gluten is macerated for a considerable time in cold water, the liquid becomes opake, and contains small films suspended, which do not soon subside. By repeated filtrations it becomes transparent; but it holds in solution gluten, which renders it frothy, and gives it the property of precipitating when mixed with oxymuriatic acid or the infusion of nutgalls. Thus gluten is to a certain extent soluble in cold water. When the water is heated, the gluten separates in the state of yellow flakes.

When kept moist, it very soon begins to decompose, and to undergo a species of fermentation. It swells, and emits air-bubbles, which Proust has ascertained to consist of hydrogen and carbonic acid gases. It emits also a very offensive odour, similar to what is emitted by putrefying animal bodies. Cadet kept gluten in a vessel for a week in a damp room. Its surface became covered with byssi, the fermentation just mentioned had commenced, and the odour was distinctly acid. In 24 days, on removing the upper crust, the gluten was found converted into a kind of paste, of a greyish-white colour, not unlike bird-lime. In that state he gave it the name of *fermented gluten*. If the gluten be still left to itself, it gradually acquires the smell and the taste of *cheese*. This curious fact was first ascertained by Rouelle junior. In that state it is full of holes, and contains the very same juices which distinguish some kinds of cheese. Proust ascertained that it contains ammonia and vinegar; bodies which Vauquelin detected in cheese; and ammonia robs both equally of their smell and flavour.

Fresh gluten does not sensibly dissolve in alcohol, which even throws down fresh gluten from water; yet in certain cases this liquid forms a solution of gluten in very small proportion.

Fermented gluten.

When the *fermented gluten* of Cadet is triturated with a little alcohol into a mucilage, and then mixed with a sufficient quantity of that liquid, a portion of it is dissolved. This solution constitutes an excellent varnish, possessed of considerable elasticity. It may be spread over paper or wood; and when dry resists other bodies, as well as most varnishes. In this state, too, it may be employed to cement china; and triturated with paints, especially vegetable colours, it forms a very good groun

When this solution is mixed with a sufficient quantity of lime, it forms a very good lute; and bits of linen dipt in it adhere very strongly to other bodies.

Ether does not sensibly dissolve gluten.

Acids act upon gluten differently, according to the peculiar properties of each.

Concentrated acetic acid dissolves it readily in considerable quantity, and without altering its nature. The solution is muddy, but permanent; and the gluten may be thrown down by means of alkalies. This acid dissolves the fermented gluten of Cadet; and the solution may be substituted for the solution in alcohol as a varnish; but it does not answer to mix it with colours.

Concentrated sulphuric acid renders it violet coloured, and at last black; inflammable air escapes, and charcoal, water, and a portion of ammonia, are formed. When nitric acid is poured on it, and heat applied, there is a quantity of azotic gas emitted; and by continuing the heat, some little oxalic acid is formed, and likewise malic acid, while a number of yellow-coloured oily flakes make their appearance in the solution.

Muriatic acid dissolves gluten with facility when its action is assisted by heat. When gluten is placed in oxymuriatic acid, it softens, and seems to dissolve, but soon coagulates again into yellow-coloured flakes, which become transparent and greenish-coloured by drying. When heated, they exhale oxymuriatic acid, and assume the appearance of common gluten. This acid has the property of precipitating gluten from water in the state of yellowish-white flakes.

Alkalies dissolve gluten when they are assisted by heat. The solution is never perfectly transparent. Acids precipitate the gluten from alkalies, but it is destitute of its elasticity. Alkalies, when much concentrated, form with it a kind of soap, converting it into oil and ammonia; which last is dissipated during the trituration.

Gluten is precipitated from water, and from some of its other solutions, by the infusion of nutgalls. The colour of the precipitate is usually yellowish-brown, and it does not dissolve though the solution be heated.

When moist gluten is suddenly dried, it swells amazingly. Dry gluten, when exposed to heat, cracks, swells, melts, blackens, exhales a fetid odour, and burns precisely like feathers or horn. When distilled, there come over water impregnated with ammonia and an empyreumatic oil; the charcoal which remains is with difficulty reduced to ashes.

SECT. III. *Of Albumen.*

Albumen. Albumen is the term by which chemists have agreed to denote the *white of egg*, and all glary tasteless substances which, like it, have the property of coagulating into a white, opaque, tough, solid substance, when heated a little under the boiling point. This substance forms a constituent of many of the fluids of animal bodies; and when coagulated, it constitutes also an important part of their solids. Substances analogous to it had been noticed by chemists in the vegetable kingdom. Scheele affirmed, as early as 1780, that the greater number of plants contained a substance analogous to curd. Fourcroy, about the year 1790, announced the existence of albumen in a variety of plants; but Proust has since shewn, that the substance which he took for albumen, and which had been already examined by Rouelle, was not possessed of the properties which characterise that animal matter. But Vauquelin has lately discovered albumen in abundance in the juice of the papaw tree; so that its existence as a vegetable principle cannot be disputed.

The *papaw tree*, the *carica papaya* of botanists, grows in Peru, &c. and in the Isle of France, where the milky juice that exudes from it is said to be employed with efficacy against the *Guinea worm*. Two specimens of this juice were brought from that island to Paris by Charpentier de Cossigny. In the one, the juice had been evaporated to dryness, and was in the state of an extract; in the other, the juice was preserved by being mixed with an equal bulk of rum. Both were subjected to a chemical analysis by Vauquelin. The first was of a yellowish-white colour, and semitransparent. Its taste was sweetish. It had no smell, and was pretty solid; but attracted moisture when kept in a damp place. The second was reddish brown, and had the smell and taste of boiled beef. When the first specimen was macerated in cold water, the greatest part of it dissolved. The solution frothed with soap. The addition of nitric acid coagulated it, and rendered it white; and when boiled, it threw down abundance of white flakes. These flakes were coagulated albumen.

Other specimens of this juice, both in the liquid and dried state, have been examined more recently by Vauquelin, and likewise by Cadet.

The essential characters of albumen are the following:

Its properties. In its natural state it is soluble in water, and forms a glary limpid liquid, having very little taste; which may be employed as a paste, and which forms a very shining varnish.

The solution is coagulated by acids, pretty much in the same way as milk is coagulated by the same re-agents.

When not too much diluted, it is coagulated also when heated to the temperature of 176°.

Albumen dissolved in water is precipitated in the state of brown flakes by the infusion of tan.

The solution is equally coagulated when mixed with alcohol.

Albumen is precipitated from water in the state of white powder by the salts of most of the white metals; such as silver, mercury, lead, tin, &c.

The juice of the papaw possessed all these properties. It therefore contained albumen. In few other vegetable productions has this substance been yet found in such abundance, or in a state in which its properties were so decidedly characteristic; but the resemblance between the curd of milk and albumen is very close, as we shall see afterwards. Now, Proust has ascertained that *almonds*, and other similar kernels from which *emulsions* are made, contain a substance which has the properties of curd.

Albumen, when burnt, emits ammonia; and when treated with nitric acid, yields azotic gas. It evidently, then, contains azote. But as it is more properly an animal than a vegetable substance, we shall defer giving any farther account of its properties till we come to treat of animal bodies.

SECT. XIV. *Of Fibrin.*

Fibrin. That peculiar substance which constitutes the fibrous part of the muscles of animals, has been called *fibrin* by chemists. A substance resembling it, as it exists in the blood, has been detected by Vauquelin in the juice of the papaw tree; the same juice which contained albumen in such plenty. Fibrin, then, must be ranked among vegetable substances.

When the juice of the papaw is treated with water, the greatest part dissolves; but there remains a substance insoluble, which has a greasy appearance. It softens in the air, and becomes viscid, brown, and semitransparent. When thrown on burning coals, it melted, let drops of grease exude, emitted the noise of meat roasting, and produced a smoke which had the odour of fat volatilized. It left behind it no residue. This substance was the *fibrin*. The resemblance between the juice of the papaw and animal matter is so close, that one would be tempted to suspect some imposition, were not the evidence that it is really the juice of a tree quite unexceptionable.

The properties of fibrin are the following:

Its properties.

1. It is tasteless, fibrous, elastic, and resembles gluten.
2. It is insoluble in water and in alcohol.
3. It is not dissolved by diluted alkalies.
4. But acids dissolve it without difficulty.
5. With nitric acid it gives out much azotic gas.
6. When distilled it yields much carbonate of ammonia and oil.
7. It soon putrefies when kept moist, becomes green, but does not acquire any resemblance to cheese.

SECT. XV. *Of the Bitter Principle.*

Bitter principle.

Many vegetable substances have an intensely bitter taste, and on that account are employed in medicine, by brewers, &c. This is the case with the wood of the *quassia amara* and *excelsa*, the common *quassia* of the shops; with the roots of the *gentiana lutea*, common *gentian;* the leaves of the *humulus lupulus*, or *hop;* the bark and wood of the *spartium scoparium*, or common broom; the flowers and leaves of the *anthemis nobilis* or *chamomile;* and many other substances. Some of these bodies owe their bitter taste to the presence of a peculiar vegetable substance differing from every other, which may be distinguished by the name of the *bitter principle.*

No chemical examination of this substance has been hitherto published; nor, indeed, are we in possession of any method of separating it from other bodies, or of ascertaining its presence. At the same time, it cannot be doubted that it possesses peculiar characters; and its action on the animal economy renders it an object of importance.

How obtained.

I. When water is digested over *quassia* for some time, it acquires an intensely bitter taste, and a yellow colour, but no smell. When water thus impregnated is evaporated to dryness in a low heat, it leaves a brownish-yellow substance, which retains a certain degree of transparency. It continues ductile for some time, but at last becomes brittle. This substance we shall consider as the bitter principle in a state of purity. If it contains any foreign body, it must be in a very minute proportion. This substance was found by the writer of this article to possess the following properties:

Its properties.

1. Its taste is intensely bitter. Colour brownish-yellow.
2. When heated, it softens, and swells, and blackens; then burns away without flaming much, and leaves a small quantity of ashes.
3. Very soluble in water and alcohol.
4. Does not alter the colour of infusion of litmus.
5. Lime-water, barytes-water, and strontian-water, occasion no precipitate. Neither is any precipitate thrown down by silicated potash, aluminated potash, or sulphate of magnesia.
6. The alkalies occasion no change in the diluted solution of the bitter principle.
7. Oxalate of ammonia occasions no precipitate.
8. Nitrate of silver renders the solution muddy, and a very soft flaky yellow precipitate falls slowly to the bottom.
9. Neither corrosive sublimate nor nitrate of mercury occasion any precipitate.
10. Nitrate of copper, and the ammonial solution of copper, produce no change; but muriate of copper gives the white precipitate, which falls when this liquid salt is dropt into water.
11. Sulphate and oxymuriate of iron occasion no change.
12. Muriate of tin renders the solution muddy, but occasions no precipitate, unless the solution be concentrated; in that case a copious precipitate falls.
13. Acetite of lead occasions a very copious white precipitate; but the nitrate of lead produces no change.
14. Muriate of zinc occasions no change.
15. Nitrate of bismuth produces no change, though when the salt is dropt into pure water a copious white precipitate appears.
16. Tartar emetic produces no change; but when the muriate of antimony is used, the white precipitate appears, which always falls when this salt is dropt into pure water.
17. Muriate and arseniate of cobalt occasion no change.
18. Arseniate of potash produces no effect.
19. Tincture of nutgalls, infusion of nutgalls, gallic acid, occasion no effect.

These properties are sufficient to convince us that the bitter principle is a substance differing considerably from all the other vegetable principles. The little effect of the different re-agents is remarkable. Nitrate of silver and acetate of lead are the only two bodies which throw it down. This precipitation cannot be ascribed to the presence of muriatic acid; for if muriatic acid were present, nitrate of lead would also be thrown down.

Another species of bitter principle.

II. Besides this purest species of bitter principle, it is probable that several others exist in the vegetable kingdom, gradually approaching by their qualities to the nature of *artificial tannin.* The second species is distinguished from the preceding, by the property which it has of striking a green colour with iron, and of precipitating that metal from concentrated solutions.

How obtained.

Mr Chenevix separated a portion of it from coffee by the following process: He digested unburnt coffee in water, and filtered the liquid. It was then treated with muriate of tin. The precipitate was edulcorated, mixed with water, and treated with sulphureted hydrogen gas. The tin was thus precipitated, and the substance with which it had been combined was dissolved by the water. The liquid was then evaporated to dryness. The substance thus obtained possessed the following properties:

Its properties.

1. Semitransparent like horn, and of a yellow colour.
2. When exposed to the air it does not attract moisture.
3. Soluble in water and in alcohol. The solution in water is semitransparent, and has a pleasant bitter taste. When the alkaline solutions are dropt into it, the colour becomes garnet red.
4. It is not precipitated from water by the alkaline carbonates. Sulphuric acid renders the solution brown, but produces no further change. Neither muriatic acid, nor phosphoric acid, nor the vegetable acids, produce any change on this solution.
5. The muriates of gold, platinum, and copper, occasion no change.
6. With solutions of iron it forms a fine green colour-

ed liquid; and when concentrated, iron throws down a green coloured precipitate. Indeed, it is almost as delicate a test of iron as tan and gallic acid.

7. Muriate of tin throws down a copious yellow precipitate. This precipitate, and that by iron, are soluble in all acids, but they lose their colour.

8. Neither lime nor strontian water occasion any precipitate in the aqueous solutions of this substance; but barytes water occasions a brown precipitate.

9. Gelatine occasions no precipitate.

Artificial bitter principle.

III. The third species may be distinguished by the name of *artificial bitter principle*, as it has been formed by the action of nitric acid on various vegetable and animal substances. It was first obtained by Haussman, while examining indigo, but he mistook its nature. Welther afterwards formed it by digesting silk in nitric acid, ascertained its properties, and gave it the name of *yellow bitter principle*; he is therefore to be considered as the real discoverer. Bartholdi afterwards procured it by treating the *white* willow with nitric acid. Mr Hatchett lately obtained it during his experiments on artificial tannin, by treating indigo with nitric acid; and about the same time Fourcroy and Vauquelin procured it by the same means, and examined its properties in detail. This substance possesses the following properties:

How obtained.

Its properties.

Its colour is a deep yellow, its taste intensely bitter. It is soluble both in water and alcohol, and has the property of dyeing silk, woollen cloth, and cotton, of a durable yellow colour. It crystallizes in elongated plates, and possesses many of the characters of an acid, combining readily with alkaline substances, and forming crystallizable salts. When potash is dropt into a concentrated solution of it, small yellow prismatic crystals are gradually deposited, consisting of bitter principle combined with potash. These crystals were examined by Welther, but it was Fourcroy and Vauquelin that ascertained their composition. They have a bitter taste, are not altered by exposure to the air, are less soluble than pure bitter principle. When thrown upon hot charcoal they burn like gunpowder, and detonate very loudly when struck upon an anvil, emitting a purple light. Ammonia dropt into the solution of bitter principle deepens its colour, and occasions a copious deposition of fine yellow spicular crystals. These are a combination of bitter principle and ammonia.

IV. Artificial tannin itself may be considered as approaching the bitter principle in many of its properties. Its taste is always intensely bitter, and the colour of the precipitates which it throws down from the metals, is similar to what takes place when artificial bitter principle is present. It is indeed possible, that the bitter taste may be owing not to the tannin, but to a portion of artificial bitter principle, which may be always formed along with the tannin; but this has not been ascertained. It is well known, that the bitter taste very easily overpowers and conceals all other tastes.

SECT. XVI. *Of Tannin.*

Tannin.

Notwithstanding the numerous experiments made upon the infusion of nutgalls, we are not in possession of a process capable of furnishing tannin in a state of purity. Hence the obscurity which still hangs over its characters. The properties of this substance, as far as known, and the different methods of procuring it hitherto proposed by chemists, have been detailed in a preceding part of this article.

Like most other vegetable substances, it seems to be susceptible of different modifications. The following are the different species of tannin which have been hitherto noticed:

Different species of tannin.

1. Tannin from nutgalls. This is the common species described in this article under the name of tannin. It precipitates iron black, and forms a firm insoluble brown precipitate with glue. The bark of oak, and most other astringent trees in this country, are supposed at present to contain this species of tannin.

2. The tannin which constitutes so large a proportion of catechu forms the second species. Its peculiar nature was first observed by Proust. It was afterwards more particularly examined by Mr Davy. It forms with iron an olive coloured precipitate.

3. The tannin of *kino* constitutes a third species. This substance is obtained from different vegetables. It was originally imported, as is supposed, from Africa; but at present the common kino of the shops is, according to Dr Duncan, an extract from the *coccoloba urifera*, or *sea-side grape*, and is brought chiefly from Jamaica. But the finest kino is the product of different species of *eucalyptus*, particularly the *resinifera*, or brown gum-tree of Botany Bay. It is an astringent substance of a dark red colour, and very brittle. It dissolves better in alcohol than water. The solution in the latter liquid is muddy; in the former transparent, and a fine crimson if sufficiently diluted. It throws down gelatine of a rose colour, and forms with salts of iron a deep green precipitate, not altered by exposure to the air.

4. The fourth variety of tannin is contained in *sumach*. This is a powder obtained by drying and grinding the shoots of the *rhus coriaria*; a shrub cultivated in the southern parts of Europe. The tan, which it contains in abundance, yields a precipitate with gelatine, which subsides very slowly, and remains in the state of a white magma without consistence.

5. The fifth variety, according to Proust, is to be found in the wood of the *morus tinctoria*, or *old fustic*, as the British dyers term it. This wood gives out an extract both to alcohol and water, which yields a precipitate with gelatine. A solution of common salt is sufficient to throw it down.

SECT. XVII. *Of the Extractive Principle.*

Extractive principle.

The word *extract* was at first applied to all those substances which were extracted from plants by means of water, and which remained behind in the state of a dry mass when the water was evaporated; consequently it included gum, jelly, and several other bodies. But, of late, it has been confined by many to a substance which exists in many plants, and which may be obtained nearly in a state of purity, according to Hermbstadt, by infusing *saffron* in water for some time, filtrating the infusion, and evaporating it to dryness. But as the word *extract* occurs even in modern authors in its original sense, we shall rather denote this substance by the phrase *extractive principle*, to prevent ambiguity.

The difficulty of obtaining the extractive principle in a separate state, and the facility with which it alters its nature, have hitherto prevented chemists from examining it with that attention to which it is entitled. It was first particularly attended to by Rouelle; but it is to Fourcroy and Vauquelin that we are chiefly indebted for ascertaining its characters. The dissertation of Vauquelin, in the *Journal de Pharmacie*, is by far the best account of extractive matter which has hitherto appeared. Many valuable facts and curious observations were published by Hermbstadt, also, in his dissertation on *extract*. But, unfortunately, the term has not been always taken by chemists in the same acceptation. Parmentier has lately published a dissertation on the *extracts* of vegetables, taken in the loose and general sense of the word, which contains much information.

The extractive principle possesses the following properties:

Its properties.

Soluble in water, and the solution is always coloured. When the water is slowly evaporated, the extractive matter is obtained in a solid state and transparent; but when the evaporation is rapid the matter is opake.

The taste of extractive is always strong; but it is very different according to the plant from which it is obtained.

Soluble in alcohol, but insoluble in ether.

By repeated solutions and evaporations, the extractive matter acquires a deeper colour, and becomes insoluble in water. This change is considered as the consequence of the absorption of the oxygen of the atmosphere, for which the extractive principle has a strong affinity. But if the solution be left to itself, exposed to the atmosphere, the extract is totally destroyed in consequence of a kind of putrefaction which speedily commences.

When oxymuriatic acid is poured into a solution containing extractive, a very copious dark yellow precipitate is thrown down, and the liquid retains but a light lemon colour. These flakes are the oxygenized *extractive.* It is now insoluble in water; but hot alcohol still dissolves it.

The extractive principle unites with alumina, and forms with it an insoluble compound. Accordingly, if sulphate, or muriate of alumina, be mixed with a solution of extractive, a flaky insoluble precipitate appears, at least when the liquid is boiled; but if an excess of acid be present, the precipitate does not always appear.

It is precipitated from water by concentrated sulphuric acid, muriatic acid, and probably by several other acids. When the experiment is made with sulphuric acid, the fumes of vinegar generally become sensible.

Alkalies readily unite with extractive, and form compounds which are insoluble in water.

The greater number of metallic oxides form insoluble compounds with extractive. Hence, many of them, when thrown into its solution, are capable of separating it from water. Hence also, the metallic salts mostly precipitate extractive. Muriate of tin possesses this property in an eminent degree. It throws down a brown powder perfectly insoluble, composed of the oxide of tin and vegetable matter.

If wool, cotton, or thread, be impregnated with alum, and then plunged into a solution of extractive, they are dyed of a fawn colour, and the liquid loses much of its extractive matter. This colour is permanent. The same effect is produced, if muriate of tin be employed instead of alum. This effect is still more complete, if the cloth be soaked in oxymuriatic acid, and then dipt into the infusion of extractive. Hence we see that the extractive matter requires no other mordant, than oxygen to fix it on cloth.

When distilled, extractive yields an acid liquid impregnated with ammonia.

It cannot be doubted, that there are many different species of extractive matter; though the difficulty of obtaining each separately has prevented chemists from ascertaining its nature with precision. Extracts are usually obtained by treating the vegetable substance from which they are to be procured with water, and then evaporating the watery solution slowly to dryness. All extracts obtained by this method have an acid taste, and redden the infusion of litmus. They all yield a precipitate while liquid, if they are mixed with ammonia. This precipitate is a compound of lime and insoluble extractive. Lime always causes them to exhale the odour of ammonia. It has been ascertained, that the extractive principle is more abundant in plants that have grown to maturity than in young plants.

Sect. XVIII. *Of the Narcotic Principle.*

Narcotic principle.

It has been long known that the milky juices which exude from certain plants, as the poppy, lettuce, &c. and the infusions of others, as of the leaves of the *digitalis purpurea*, have the property of exciting sleep, or, if taken in large enough dozes, of inducing a state resembling apoplexy, and terminating in death. How far these plants owe these properties to certain common principles which they possess is not known; though it is exceedingly probable that they do. But as a *peculiar substance* has been detected in *opium*, the most noted of the narcotic preparations, which possesses narcotic properties in perfection, we are warranted, till further experiments elucidate the subject, to consider it as the *narcotic principle*, or at least as one species of the substances belonging to this genus.

How obtained.

Opium is obtained from the *papaver album*, or white poppy, a plant which is cultivated in great abundance in India and the East. The poppies are planted in a fertile soil and well watered. After the flowering is over, and the seed capsules have attained nearly their full size, a longitudinal incision is made in them about sun-set, for three or four evenings in succession. From these incisions there flows a milky juice, which soon concretes, and is scraped off the plant and wrought into cakes. In this state it is brought to Europe.

Its properties.

Opium, thus prepared, is a tough brown substance, has a peculiar smell, and a nauseous bitter acrid taste. It is a very compound substance, containing sulphate of lime, sulphate of potash, an oil, a resinous body, an extractive matter, gluten, mucilage, &c. besides the peculiar narcotic principle, to which, probably, it owes its virtues as a narcotic.

When water is digested upon opium, a considerable portion of it is dissolved, the water taking up several of its constituents. When this solution is evaporated to the consistence of a syrup, a gritty precipitate begins to appear, which is considerably increased by diluting the liquid with water. It consists chiefly of three ingredients; namely, resin, oxygenized extractive, and the peculiar narcotic principle, which is crystallized. When alcohol is digested on this precipitate, the resin and narcotic substance are taken up, while the oxygenized extractive remains behind. The narcotic principle falls down in crystals as the solution cools, still however coloured with resin. But it may be obtained tolerably pure by repeated solutions and crystallizations.

Water is incapable of dissolving the whole of opium. What remains behind still contains a considerable portion of narcotic principle. When alcohol is digested on this residuum, it acquires a deep red colour; and deposites, on cooling, crystals of narcotic principle, coloured by resin, which may be purified by repeated crystallizations. The narcotic principle obtained by either of these methods possesses the following properties.

Its colour is white. It crystallizes in rectangular prisms with rhomboidal bases. It has neither taste nor smell.

It is insoluble in cold water, soluble in about 400 parts of boiling water, but precipitates again as the solution cools. The solution in boiling water does not affect vegetable blues.

It is soluble in 24 parts of boiling alcohol and 100 parts of cold alcohol. When water is mixed with the solution, the narcotic principle precipitates in the state of a white powder.

Hot ether dissolves it, but lets it fall on cooling.

When heated in a spoon, it melts like wax. When distilled, it froths and emits white vapours, which condense into a yellow oil. Some water and carbonate of ammonia pass into the receiver; and at last carbonic acid gas, ammonia, and carbureted hydrogen gas, are disengaged. There remains a bulky coal, which yields traces of potash. The oil obtained by this process is viscid, and has a peculiar aromatic smell and acrid taste.

It is very soluble in all acids. Alkalies throw it down from these solutions in the state of a white powder.

Alkalies render it rather more soluble in water. When they are saturated with acids, the narcotic principle falls down in the state of a white powder, which is redissolved by adding an excess of acid.

Volatile oils, while hot, dissolve it; but, on cooling, they let it fall in an oleaginous state at first, but it gradually crystallizes.

When treated with nitric acid, it becomes red and dissolves; much oxalic acid is formed, and a bitter substance remains behind.

When potash is added to the aqueous solution of opium, the narcotic principle is thrown down; but it retains a portion of the potash.

Its solubility in water and alcohol, when immediately extracted from opium, seems to be owing to the presence of *resin* and *extractive matter*, both of which render it soluble.

It possesses the properties of opium in perfection. Dérosne tried it upon several dogs, and found it more powerful than opium. Its bad effects were counteracted by causing the animals to swallow vinegar. This substance is known to be of equal service in counteracting the effects of opium. Dérosne supposes that the efficacy of vinegar may be owing to the readiness with which it dissolves the narcotic principle.

SECT. XIX. *Of Oils.*

Oils.

There are two species of oils; namely, *fixed* and *volatile*; both of which are found abundantly in plants.

Fixed oils.

1. Fixed oil is only found in the seeds of plants, and is almost entirely confined to those which have two cotyledons; as linseed, almonds, beech root, poppy seed, rape seed, &c. Sometimes, though rarely, it is found in the pulp which surrounds the stone of certain fruits. This is the case with the olive, which yields the most abundant and most valuable species of fixed oil. The bicotyledonous seeds, besides oil, contain also a mucilaginous substance; and they have all the character of forming, when bruised in water, a milky liquid, known by the name of *emulsion*.

The following is a list of the plants which yield the fixed oils which usually occur in commerce.

Plants which yield fixed oils.

1. Linum usitatissimum et perenne	Linseed oil
2. Corylus avellana 3. Juglans regia	Nut oil
4. Papapaver somniferum	Poppy oil
5. Cannabis sativa	Hemp oil
6. Sesamum orientale	Oil of Sesamum
7. Olea Europea	Olive oil
8. Amygdalus communis	Almond oil
9. Guilandina Mohringa	Oil of behen
10. Cucurbita pepo et melopepo	Cucumber oil
11. Fagus sylvatica	Beech oil
12. Sinapis nigra et arvensis	Oil of mustard
13. Helianthus annuus et perennis	Oil of sunflower
14. Brassica napus et campestris	Rape seed oil
15. Ricinus communis	Castor oil
16. Nicotiana tabacum et rustica	Tobacco seed oil
17. Prunus domestica	Plum kernel oil
18. Vitis vinifera	Grape seed oil
19. Theobroma cacao	Butter of cacao
20. Laurus nobilis	Laurel oil
21. Arachis hypogæa	Ground nut oil

Volatile oils.

2. Volatile oils are found in every part of plants except the cotyledons of the seeds, where they never occur. The root, the stem, the leaves, the flower, the rind or pulp of the fruit of a variety of plants, are loaded with volatile oils, from which they are extracted by expression or by distillation. The numbers of these oils is so great that it baffles all description. Almost every plant which is distinguished by a peculiar odour contains a volatile oil, to which it is indebted for that odour.

The following Table contains a pretty copious list of plants which yield volatile oils. The part of the plant from which it is extracted, and the English name of the oil, are added in separate columns.

Plants which yield volatile oils.

Plants.	*Parts.*	*Oil of*	*Colour.*
1. Artemisia absynthium	Leaves	Wormwood	Green
2. Acorus calamus	Root	Sweet flag	Yellow
3. Myrtus pimenta	Fruit	Jamaica pep. ‡	Yellow
4. Anethum graveolens	Seeds	Dill	Yellow
5. Angelica archangelica	Root	Angelica	
6. Pimpinella	Seeds	Anise	White
7. Illicium anisatum	Seeds	Stellat. anise	Brown
8. Artemisia vulgaris	Leaves	Mugwort	
9. Citrus aurantium	Rind of the fruit	Bergamotte	Yellow
10. Melaleuca leucadendron	Leaves	Cajeput	Green
11. Eugenia caryophyllata	Capsules	Cloves ‡	Yellow
12. Carum carvi	Seeds	Caraways	Yellow
13. Amomum cardamomum	Seeds	Card. seeds	Yellow
14. Carlina acaulis	Roots		White
15. Scandix chærefolium	Leaves	Chervil	Sulph. yel.
16. Matricaria chamomilla	Petals	Chamomile	Blue
17 Laurus cinnamomum	Bark	Cinnamon ‡	Yellow
18. Citrus medica	Rind of the fruit	Lemons	Yellow
19. Cochlearia officinalis	Leaves	Scurvy grass	Yellow
20. Copaifera officinalis	Extract	Copaiba	White
21. Coriandrum sativum	Seeds	Coriand. seed	White
22. Crocus sativus	Pistils	Saffron ‡	Yellow
23. Piper cubeba	Seeds	Cubeb peb	Yellow
24. Laurus culilaban	Bark	Culilaban	Br. yel.
25. Cuminum cyminum	Seeds	Cummi	Yellow
26. Inula helenium	Roots	Elecampane	White
27. Anethum fæniculum	Seeds	Fennel	White
28. Croton elutheria	Bark	Cascarilla	Yellow
29. Maranta galanga	Roots	Galanga	Yellow
30. Hyssopus officinalis	Leaves	Hyssop	Yellow
31. Juniperus communis	Seeds	Juniper	Green
32. Lavendula spica	Flowers	Lavender	Yellow
33. Laurus nobilis	Berries	Laurel	Brownish
34. Prunus laurocerasus	Leaves	Lauroceras. ‡	
35. Levisticum ligusticum	Roots	Lovage	Yellow
36. Myristica moschata	Seeds	Mace	Yellow
37. Origanum majorana	Leaves	Marjoram	Yellow
38. Pistacia lentiscus	Resin	Mastich	Yellow
39. Matricaria parthenium	Plant	Motherwort	Blue
40. Melissa officinalis	Leaves	Balm	White
41. Mentha crispa	Leaves		White
42. ——— piperitis	Leaves	Peppermint	Yellow
43. Achillea millefolium	Flowers	Millefoil	Blue and green
44. Citrus aurantium	Petals	Neroli	Orange
45. Origanum creticum	Flowers	Spanish hop	Brown
46. Apium petroselinum	Roots	Parsley	Yellow

Plants.	Parts.	Oil of	Colour.
47. Pinus sylvestris et abies	Wood and resin	Turpentine	Colourless
48. Piper nigrum	Seeds	Pepper	Yellow
49. Rosmarinus officinalis	Plant	Rosemary	Colourless
50. Mentha pulegium	Flowers	Pennyroyal	Yellow
51. Genista canariensis	Root	Rhodium	Yellow
52. Rosa centifolia	Petals	Roses	Colourless
53. Ruta graveolens	Leaves	Rue	Yellow
54. Juniperus sabina	Leaves	Savine	Yellow
55. Salvia officinalis	Leaves	Sage	Green
56. Santalum album	Wood	Santalum ‡	Yellow
57. Laurus sassafras	Root	Sassafras	Yellow
58. Satureia hortensis	Leaves	Satureia	Yellow
59. Thymus serpillum	Leaves and flower	Thyme	Yellow
60. Valeriana officinalis	Root	Valerian	Green
61. Kæmpferia rotunda	Root	Zedoary	Greenish blue
62. Amomum Zinziber	Root	Ginger	Yellow
63. Andropogon schœnanthum		Sira	Brown

The oils marked ‡ sink in water. They yield also a fixed oil.

Several of the gum resins, as *myrrh* and *galbanum*, yield likewise an essential oil, and likewise the balsam of *benzoin*, &c.

Sect. XX. *Of Wax.*

Wax.

The upper surface of the leaves of many trees is covered with a varnish, which may be separated and obtained in a state of purity by the following process:

How obtained.

Digest the bruised leaves, first in water and then in alcohol, till every part of them which is soluble in these liquids, be extracted. Then mix the residuum with six times its weight of a solution of pure ammonia, and, after sufficient maceration, decant off the solution, filter it, and drop into it, while it is incessantly stirred, diluted sulphuric acid, till more be added than is sufficient to saturate the alkali. The varnish precipitates in the form of a yellow powder. It should be carefully washed with water, and then melted over a gentle fire.

Its properties.

Mr Tingry first discovered that this varnish possesses all the properties of *bees wax*. Wax, then, is a vegetable product. Several plants contain wax in such abundance as to make it worth while to extract it from them. But let us, in the first place, consider the properties of bees wax, the most common and important species. This substance, as Huber has demonstrated, contrary to the generally received opinion, is prepared by the bees from honey or sugar, the latter yielding the greatest proportion of it.

Wax, when pure, is of a whitish colour; it is destitute of taste, and has scarcely any smell. Bees wax, indeed, has a pretty strong aromatic smell; but this seems chiefly owing to some substance with which it is mixed; for it disappears almost completely by exposing the wax, drawn out into thin ribands, for some time to the atmosphere. By this process, which is called *bleaching*, the yellow colour of the wax disappears, and it becomes very white. Bleached wax is not affected by the air.

The specific gravity of unbleached wax varies from 0.9000 to 0.9650; that of white wax from 0.8203 to 0.9662.

Wax is insoluble in water; nor are its properties altered though kept under that liquid.

When heat is applied to wax it becomes soft; and at the temperature of 142°, if unbleached, or of 155° if bleached, it melts into a colourless transparent fluid, which concretes again, and resumes its former appearance as the temperature diminishes. If the heat be still farther increased, the wax boils and evaporates; and if a red heat be applied to the vapour, it takes fire and burns with a bright flame. It is this property which renders wax so useful for making candles.

Wax is scarcely acted on by alcohol when cold, but boiling alcohol dissolves it.

Ether has but little action on wax while cold; but when assisted by heat, it takes up about one-twentieth of its weight of it, and lets the greatest part precipitate on cooling.

Wax combines readily with fixed oils when assisted by heat, and forms with them a substance of greater or less consistency, according to the quantity of oil. This composition, which is known by the name of *cerate*, is much employed by surgeons.

The volatile oils also dissolve wax when heated. This is well known, at least, to be the case with oil of turpentine. A part of the wax precipitates usually as the solution cools, but of a much softer consistence than usual, and therefore containing oil.

The fixed alkalies combine with it, and form a compound which possesses all the properties of common soap. When boiled with a solution of fixed alkalies in water, the liquid becomes turbid, and after some time the soap separates and swims on the surface. It is precipitated from the alkali by acids in the state of flakes, which are the wax very little altered in its properties.

The acids have but little action on wax; even oxymuriatic acid, which acts so violently on most bodies, produces no other change on it than that of rendering it white. This property which wax possesses, of resisting the action of acids, renders it very useful as a lute to confine acids properly in vessels, or to prevent them from injuring a common cork.

Mr Lavoisier contrived to burn wax in oxygen gas. The quantity of wax consumed was 21.9 grains. The oxygen gas employed in consuming that quantity amounted to 66.55 grains. Consequently, the substances consumed, amounted to 88.45 grains. After the combustion, there were found in the glass vessel 62.58 grains of carbonic acid, and a quantity of water, which was supposed to amount to 25.87 grains. These were the only products.

Composition according to Lavoisier.

From this experiment he concluded, that 100 parts of wax are composed of

82.28	carbon
17.72	hydrogen
100.00	

According to Thenard and Gay-Lussac.

But according to the experiments of Thenard and Gay-Lussac, it is composed of

Carbon	81.784
Hydrogen	12.672
Oxygen	5.544
	100

Myrtle wax.

The myrtle wax of North America is obtained from the *myrica cerifera*. The *myrica cerifera* is a shrub which grows abundantly in Louisiana and other parts of North America. It produces a berry about the size of a pepper corn. A very fertile shrub yields nearly seven pounds. From the observations of Cadet, we learn that the wax forms the outer covering of the berries. The wax thus obtained is of a pale green colour. Its specific gravity is 1.0150. It melts at the temperature of 109°: when strongly heated it burns with a white flame, produces little smoke, and during the combustion emits an agreeable aromatic odour. Water does not act upon it. Alcohol, when hot, dissolves one tenth of its weight, but lets most of it fall again on cooling. Hot ether dissolves about one-fourth of its weight; and when slowly cooled, deposites it in crystalline plates, like spermaceti. The ether acquires a green colour, but the wax becomes nearly white. Oil of turpentine, when assisted by heat, dissolves it sparingly. Alkalies act upon it nearly as on bees wax. The same remark applies to acids. Sulphuric acid, when assisted by heat, dissolves about one-twelfth of its weight, and is converted into a thick dark brown mass.

The Chinese extract a wax from various vegetables, which they manufacture into candles, and of which they form many delicate ornaments which are brought to Europe.

Sect. XXI. *Camphor.*

Camphor.

The substance called *camphor*, though unknown to the Greeks and Romans, seems to have been long known in the East. When it was first brought to Europe does not appear, though it seems to have been introduced by the Arabians.

How obtained.

It comes to Europe chiefly from Japan. It is obtained from the *laurus camphora*, a tree common in the East, by distilling the wood along with water in large iron pots, on which are fitted earthen heads stuffed with straw. The camphor sublimes, and concretes upon the straw in the form of a grey powder. It is afterwards refined in Holland by a second sublimation. The vessels are of glass, and somewhat of the shape of a turnip, with a small mouth above loosely covered with paper. According to Ferber, about one-fourth of pounded chalk is mixed with crude camphor; but others assure us that there is no addition whatever employed.

Its properties.

Camphor thus confined is a white brittle substance, having a peculiar aromatic odour, and a strong hot acrid taste. Its specific gravity is 0.9887.

It is not altered by atmospheric air; but it is so volatile, that if it be exposed during warm weather in an open vessel, it evaporates completely. When sublimed in close vessels it crystallizes in hexagonal plates or pyramids.

It is insoluble in water; but it communicates to that liquid a certain portion of its peculiar odour.

It dissolves readily in alcohol, and is precipitated again by water. According to Neumann, well rectified alcohol dissolves three-fourths of its weight of camphor. By distillation the alcohol passes over first, and leaves the camphor. This property affords an easy method of purifying camphor. Dissolve the camphor in alcohol, distil off the spirit, and melt the camphor into a cake in a glass vessel.

Camphor is soluble also in oils, both fixed and volatile. If the solution be made by means of heat, as it cools part of the camphor precipitates, and assumes the form of plumose or feather-like crystals.

Camphor is not acted on by alkalies, either pure or in the state of carbonates. Pure alkalies, indeed, seem to dissolve a little camphor; but the quantity is too small to be perceptible by any other quality than its odour. Neither is it acted on by any of the neutral salts which have hitherto been tried.

Acids dissolve camphor without effervescence, and in general it may be precipitated unaltered from the recent solution.

When heat is applied to camphor it is volatilized. If the heat be sudden and strong, the camphor melts before it evaporates; and it melts, according to Venturi, at the temperature of 300°; according to Romieu, at 421°. It catches fire very readily, and emits a great deal of flame as it burns, but it leaves no residuum. It is so inflammable that it continues to burn even on the surface of water. When camphor is set on fire in a large glass globe, filled with oxygen gas, and containing a little water, it burns with a very bright flame, and produces a great deal of heat. The inner surface of the glass is soon covered with a black powder, which has all the properties of charcoal; a quantity of carbonic acid gas is evolved; the water in the globe acquires a strong smell, and is impregnated with carbonic acid and camphoric acid.

Different species of camphor.

There are several species of camphor which have been examined by chemists, and which differ considerably from each other in their properties. The most remarkable are *common camphor*, the *camphor of volatile oils*, and the *camphor* obtained by treating *oil of turpentine* with *muriatic acid*.

Common camphor, obtained by distillation from the *laurus camphora*, is the substance which has been described in the preceding part of this Chapter. In Borneo and Sumatra camphor is procured from the *laurus sumatrensis*; but as none of this camphor is brought to Europe, we do not know how far it agrees with common camphor in its properties The *laurus cinnamomum* likewise yields camphor.

The second species of camphor seems to exist in a great variety of plants, and is held in solution by the volatile oils extracted from them. Neumann obtained it from oils of thyme, marjoram, cardomum; Hermann, from oils extracted from various species of mint. Cartheuser obtained it from the roots of the *maranta galanga*, *kæmpferia rotunda*, *amomum zinziber*, *laurus cassia*, and rendered it probable that it is contained in almost all the labiated plants. It has been supposed to exist in these plants combined with volatile oil. Proust has shown how it may be extracted, in considerable quantity, from many volatile oils.

From the observations of Mr John Brown, there is reason to believe that the camphor from oil of thyme differs from common camphor in several respects. It does not appear to form a liquid solution either with nitric or sulphuric acid; nor is it precipitated from nitric acid in powder like common camphor, but in a glutinous mass.

The artificial camphor yielded by oil of turpentine, when saturated with muriatic acid gas, was discovered by Mr Kind, apothecary in Eutin, while employed in making a medicine called the *liquor arthriticus Pottii*. He put a quantity of oil of turpentine into a Woulfe's bottle, and caused a current of muriatic acid gas, separated from common salt by sulphuric acid, to pass through it. The salt used was of the same weight with the oil of turpentine. At first the oil became yellow, then brown, and at last became almost solid, from the formation of a great number of crystals in it, which possessed the properties of camphor.

The proportion of muriatic gas found to answer best, is what can be separated by sulphuric acid and heat from a quantity of common salt equal in weight to the oil of turpentine employed. The camphor produced amounts nearly to one-half of the oil of turpentine.

The camphor thus produced was very white; it had a peculiar odour, in which that of the oil of turpentine could be distinguished. When washed with water it became beautifully white, and gave no longer signs of containing an acid, but still had the smell of oil of turpentine. Water containing some carbonate of potash deprived it of part of this odour, but not the whole. When mixed with its own weight of charcoal powder, wood-ashes, quicklime, or porcelain clay, and sublimed, it was obtained in a state of purity.

Its smell, when pure, resembles that of common camphor, but is not so strong. Its taste also resembles that of camphor. It swims on water, to which it communicates its taste, and burns upon its surface. It dissolves completely in alcohol, and is precipitated by water. Nitric acid, of the specific gravity 1.261, had no action on it, though it readily dissolves common camphor; but concentrated nitric acid dissolves it with the disengagement of nitrous gas; and water does not precipitate it from its solution as it does common camphor. Acetic acid does not dissolve it. When heated it sublimes without decomposition; and when set on fire it burns like camphor.

Sect. XXII. *Of Bird lime.*

Bird-lime.

The vegetable principle to which we give the name of *bird-lime*, was first examined by Vauquelin, who found it possessed of properties different from every other. It was found collected on the epidermis of a plant brought to Europe by Michaud, and called *robinia viscosa* by Cels; constituting a viscid substance, which made the fingers adhere to the young twigs. From the late analysis of *bird-lime* by Bouillon la Grange, it is obvious that it owes its peculiar properties to the presence of an analogous substance, which indeed constitutes the essential part of that composition. Hence the reason why we have given the name of *bird-lime* to the principle itself.

Properties of natural bird-lime.

Natural bird-lime (or that which exudes spontaneously from plants), possesses the following properties:

Its colour is green; it has no sensible taste or smell; is extremely adhesive; softens by the heat of the fingers, and sticks to them with great obstinacy. When heated it melts, swells up, and burns with a considerable flame, leaving a bulky charcoal behind it. It does not dissolve in water; alcohol has but little action on it, especially when cold. By the assistance of heat it dissolves a portion of it; but on cooling, allows the greatest part to precipitate again. When exposed to the air it continues glutinous, never becoming hard and brittle like the resins.

It combines readily with oils. Ether is its true solvent, dissolving it readily without the assistance of heat. The solution is of a deep green colour. The alkalies do not combine with it; the effect of the acids was not tried. These properties are sufficient to distinguish bird-lime from every other vegetable principle.

Artificial bird-lime.

Artificial bird-lime is prepared from different substances in different countries. The berries of the misletoe are said to have been formerly employed. They were pounded, boiled in water, and the hot water poured off. At present bird-lime is usually prepared from the middle bark of the holly. The process followed in England, as described by Geoffroy, is as follows: The bark is boiled in water seven or eight hours, till it becomes soft. It is then laid in quantities in the earth, covered with stones, and left to ferment or rot for a fortnight or three weeks. By this fermentation it changes to a mucilaginous consistency. It is then taken from the pits, pounded in mortars to a paste, and well washed with river water. Bouillon la Grange informs us, that at Nogent le Rotrou bird-lime is made by cutting the middle bark of the holly into small pieces, fermenting them in a cool place for a fortnight, and then boiling them in water, which is afterwards evaporated. At Commerci various other plants are used.

Its colour is greenish, its flavour sour, and its consistence gluey, stringy, and tenacious. Its smell is similar to that of linseed oil. When spread on a glass plate, and exposed to the air and light, it dries, becomes brown, loses its viscidity, and may be reduced to powder; but when water is added to it, the glutinous property returns. It reddens vegetable blues.

When gently heated it melts, and emits an odour like that of animal oils. When heated on red hoat coals, it burns with a lively flame, and gives out a great deal of smoke, leaving a white ash, composed of carbonet of lime, alumina, iron, sulphate, and muriate of potash.

Water has little action on bird-lime. When boiled in water the bird-lime becomes more liquid, but recovers its original properties when the water cools. The water, by this treatment, acquires the property of reddening vegetable blues, and when evaporated leaves a mucilaginous substance, which may be likewise separated by alcohol.

A concentrated solution of potash forms with bird-lime a whitish magma, which becomes brown by evaporation, while ammonia separates. The compound thus formed is less viscid than bird-lime, and in smell and taste resembles soap. In alcohol and water it dissolves almost completely, and possesses properties similar to those of soap.

Weak acids soften bird-lime, and partly dissolve it; strong acids act with more violence. Sulphuric acid renders it black; and when lime is added to the solution, acetic acid and ammonia separate. Nitric acid cold has little effect; but when assisted by heat it dissolves the bird-lime; and the solution, when evaporated, leaves behind it a hard brittle mass. By treating this mass with nitric acid, a new solution may be obtained, which by evaporation yields malic and oxalic acids, and a yellow matter which possesses several of the properties of wax. Cold muriatic acid does not act on bird-lime; hot muriatic acid renders it black.

Alcohol of the specific gravity 0.817 dissolves bird-lime at a boiling heat. On cooling, it lets fall a yellow matter similar to wax. The filtered liquid is bitter, nauseous, and acid. Water precipitates a substance similar to resin.

Sulphuric ether dissolves bird-lime readily, and in great abundance. The solution is greenish. When mixed with water, an oily substance separates, which has some resemblance to linseed oil. When evaporated, a greasy substance is obtained, having a yellow colour and the softness of wax. Oil of turpentine dissolves bird-lime readily.

Sect. XXIII. *Of Resins.*

Resins.

It is at present the opinion of chemists, that *resins* stand in the same relation to the *volatile* oils that *wax* does to the *fixed*. Wax is considered as a fixed oil saturated with oxygen; resins, as volatile oils saturated with the same principle.

Resins often exude spontaneously from trees; they often flow from artificial wounds, and not uncommonly are combined at first with volatile oil, from which they are separated by distillation. The reader can be at no loss to form a notion of what is meant by *resin*, when he is informed that common *rosin* furnishes a very perfect example of a resin, and that it is from this substance that the whole genus derived their name: for rosin is frequently denominated *resin*.

I. Resins may be distinguished by the following properties:

General properties.

They are solid substances, naturally brittle; have a certain degree of transparency, and a colour most commonly inclining to yellow. Their taste is more or less acrid, and not like that of volatile oils; but they have no smell unless they happen to contain some foreign body. They are all heavier than water. They are all non-conductors of electricity; and when excited by friction, their electricity is negative.

Their specific gravity varies considerably.

When exposed to heat, they melt; and if the heat be increased, they take fire, and burn with a strong yellow flame, emitting at the same time a vast quantity of smoke.

They are all insoluble in water whether cold or hot; but when they are melted along with water, or mixed with volatile oil, and then distilled with water, they seem to unite with a portion of that liquid; for they become opake, and lose much of their brittleness. This at least is the case with common rosin.

They are all, with a few exceptions, soluble in alcohol, especially when assisted by heat. The solution is usually transparent; and when the alcohol is evaporated, the resin is obtained unaltered in its properties.

Several of them are soluble in fixed oils, especially in the drying oils. The greater number are soluble in the volatile oils; at least in oil of turpentine, the one commonly employed.

Mr Hatchett first examined the action of fixed alkalies on resins, and ascertained, contrary to the received opinion of chemists, that alkaline leys dissolve them with facility. He reduced a quantity of common rosin to powder, and gradually added it to a boiling lixivium of carbonate of potash; a perfect solution was obtained of a clear yellow colour, which continued after long exposure to the air. The experiment succeeded equally with carbonate of soda, and with solutions of pure potash, or soda. Every other resin was dissolved as well as *rosin*.

These alkaline solutions of resins have the properties of soap, and may be employed as detergents. When mixed with an acid, the resin is separated in flakes, usually of a yellow colour, and not much altered in its nature.

Ammonia acts but imperfectly upon resins, and does not form a complete solution of any of those bodies hitherto tried.

It was the received opinion of chemists, that acids do not act upon resins. Mr Hatchett first ascertained this opinion also to be erroneous, and showed that most of the acids dissolve resins with facility, producing different phenomena according to circumstances.

When sulphuric acid is poured upon any of the resins in powder, it dissolves them in a few minutes. At first the solution is transparent, of a yellowish brown colour, and of the consistency of a viscid oil, and the resin may be precipitated nearly unaltered by the addition of water. If the solution be placed on a sand bath, its colour becomes deeper, sulphurous acid gas is emitted, and it becomes very thick, and of an intense black.

Nitric acid likewise dissolves the resins with facility, but not without changing their nature. Mr Hatchett was first led to examine the action of this acid on resins, by observing that resins are thrown down by acids from their solutions in alkalies in the state of a curdy precipitate; but when nitric acid is added in excess, the whole of the precipitate is re-dissolved in a boiling heat. He poured nitric acid of the specific gravity 1.38, on powdered rosin in a tubulated retort; and by repeated distillation formed a complete solution of a brownish yellow colour. The solution takes place much sooner in an open matrass than in close vessels. The solution continues permanent, though left exposed to the air. It becomes turbid when water is added; but when the mixture is boiled, the whole is re-dissolved.

When the digestion of nitric acid upon a resinous substance is continued long enough, and the quantity of acid is sufficient, the dissolved resin is completely changed; it is not precipitated by water; and by evaporation, a viscid substance of a deep yellow colour is obtained, equally soluble in water and alcohol, and seemingly intermediate between resin and extractive. If the abstraction of nitric acid be repeated, this substance gradually assumes the properties of artificial tannin. Thus it appears that nitric acid gradually alters the nature of resin, producing a suite of changes which terminate in artificial tannin, upon which nitric acid has no action.

Muriatic acid and acetic acid dissolve resin slowly, and it may be precipitated again from them unaltered.

When resins are subjected to destructive distillation, we obtain carbureted hydrogen and carbonic acid gas, a very small portion of acidulous water, and much empyreumatic oil. The charcoal is light and brilliant, and contains no alkali.

Resins of most importance, viz.

II. Having now described the general properties of resinous bodies, it will be proper to take a more particular view of those of them which are of the most importance, that we may ascertain how far each possesses the general characters of resins, and by what peculiarities it is distinguished from the rest. The most distinguished of the resins are the following.

Rosin.

1. *Rosin*.—This substance is obtained from different species of *fir*; as the *pinus abies*, *sylvestris*, *larix*, *balsamea*. It is well known that a resinous juice exudes from the *pinus sylvestris*, or common Scotch fir, which hardens into tears. The same exudation appears in the *pinus abies*, or spruce fir. These tears constitute the substance called *thus*, or common frankincense. When a portion of bark is stripped off these trees, a liquid juice flows out, which gradually hardens. This juice has obtained different names according to the plant from which it comes. The *pinus sylvestris* yields *common turpentine*; the *larix*, *Venice turpentine*; the *balsamea*, *balsam of Canada*, &c. All these juices, which are commonly distinguished by the name of turpentine, are considered as composed of two ingredients; namely, oil of turpentine and rosin.

Composition.

According to the experiments of Thenard and Gay Lussac, it is composed of

Carbon	75.944
Oxygen . . .	13.337
Hydrogen . . .	10.719
	100.000

Mastich.

2. *Mastich*.—This resin is obtained from the *pistacia lentiscus*; a tree which grows in the Levant, particularly in the island of Chios. When transverse incisions are made into this tree, a fluid exudes, which soon concretes into yellowish semitransparent brittle grains. It softens when kept in the mouth, but imparts very little taste. When heated, it melts and exhales a fragrant odour. Its taste is slight, but not unpleasant. In Turkey, great quantities of it are said still to be chewed for sweetening the breath, and strengthening the gums. It is to this use of the resin as a masticatory that it is supposed to owe its name. Mastich does not dissolve completely in alcohol; a soft elastic substance separates during the solution. The nature of this insoluble portion was first

examined by Kind, who found it possessed of all the properties of caoutchouc. These experiments have lately been repeated by Mr Matthews with a similar result. Mr Brande, however, has observed, that when this insoluble substance is dried, it becomes brittle, in which respect it differs from caoutchouc. He has observed also, that by passing a current of oxymuriatic gas through the alcoholic solution of mastich, a tough elastic substance is thrown down, precisely similar to the original insoluble portion.

Sandarach,

3. *Sandarach.*—This resin is obtained from the *juniperus communis*, or common juniper. It exudes spontaneously, and is usually in the state of small round tears of a brown colour, and semitransparent, not unlike mastich, but rather more transparent and brittle. When chewed it does not soften as mastich does, but crumbles to powder. Mr Matthews found it almost completely soluble in eight times its weight of alcohol. The residue was extraneous matter. It does not dissolve in tallow or oil, as common resin does.

Elemi,

4. *Elemi.*—This resin is obtained from the *amyris elemifera*; a tree which grows in Canada and Spanish America. Incisions are made in the bark during dry weather, and the resinous juice which exudes is left to harden in the sun. It comes to this country in long roundish cakes wrapped in flag leaves. It is of a pale yellow colour, semitransparent; at first softish, but it hardens by keeping. Its smell is at first strong and fragrant, but it gradually diminishes.

Tacamahac,

5. *Tacamahac.*—This resin is obtained from the *fagara octandra*, and likewise, it is supposed, from the *populus balsamifera*. It comes from America in large oblong masses wrapt in flag leaves. It is of a light brown colour, very brittle, and easily melted when heated. When pure it has an aromatic smell between that of lavender and musk.

Animé,

6. *Animé.*—This resin is obtained from the *hymenæa courbaril*, or locust tree, which is a native of North America. Animé resembles copal very much in its appearance; but is readily soluble in alcohol, which copal is not: this distinguishes them. It is said to be very frequently employed in making varnishes. Alcohol dissolves it completely.

Ladanum,

7. *Ladanum or labdanum.*—This resin is obtained from the *cystus creticus*, a shrub which grows in Syria and the Grecian Islands. The surface of this shrub is covered with a viscid juice, which, when concreted, forms ladanum. It is collected, while moist, by drawing over it a kind of rake with thongs fixed to it. From these thongs it is afterwards scraped with a knife. It is always mixed with dust and sand, sometimes in great abundance. The best is in dark coloured masses, almost black, and very soft, having a fragrant odour and a bitterish taste. The impurities, even in the best kinds, amount to about one-fourth.

Botany Bay resin,

8. *Botany Bay resin.*—This resin is said to be the produce of the *acarois resinifera*; a tree which grows abundantly in New Holland, especially near Botany Bay. Specimens of it were brought to London about the year 1799, where it was tried as a medicine.

The resin exudes spontaneously from the trunk of the singular tree which yields it, especially if the bark be wounded. It is at first fluid, but becomes gradually solid when dried in the sun. It consists of pieces of various sizes, of a yellow colour, unless when covered with a greenish grey crust. It is firm, yet brittle; and when pounded, does not stick to the mortar nor cake. In the mouth it is easily reduced to powder without sticking to the teeth. It communicates merely a slight sweetish astringent taste. When moderately heated, it melts; on hot coals it burns to a coal, emitting a white smoke, which has a fragrant odour somewhat like storax. When thrown into the fire, it increases the flame like pitch. It communicates to water the flavour of storax, but is insoluble in that liquid. When digested in alcohol, two-thirds dissolve: the remaining third consists of one part of extractive matter, soluble in water, and having an astringent taste; and two parts of woody fibre and other impurities, perfectly tasteless and insoluble. The solution has a brown colour, and exhibits the appearance and the smell of a solution of benzoin. Water throws it down unaltered. When distilled, the products were water and empyreumatic oil, and charcoal; but it gives no traces of any acid, alkali, or salt, not even when distilled with water.

Copal,

9. *Copal.*—This substance, which deserves particular attention from its importance as a varnish, and which at first sight seems to belong to a distinct class from the resins, is obtained, it is said, from the *rhus copallinum*, a tree which is a native of North America; but the best sort of copal is said to come from Spanish America, and to be the produce of different trees. No less than eight species are enumerated by Hernandez.

Copal is a beautiful white resinous substance, with a slight tint of brown. It is sometimes opaque, and sometimes almost perfectly transparent. When heated, it melts like other resins; but it differs from them in not being soluble in alcohol, nor in oil of turpentine without peculiar management. Neither does it dissolve in the fixed oils with the same ease as the other resins. It resembles gum animé a little in appearance; but is easily distinguished by the solubility of this last in alcohol, and by its being brittle between the teeth, whereas animé softens in the mouth. The specific gravity of copal varies, according to Brisson, from 1.045 to 1.139. Mr Hatchett found it soluble in alkalies and nitric acid with the usual phenomena; so that in this respect it agrees with the other resins. The solution of copal in alkalies he found indeed opalescent, but it is nevertheless permanent. It deserves attention, that he found rosin, when dissolved in nitric acid, and then thrown down by an alkali, to acquire a smell resembling that of copal.

When copal is dissolved in any volatile liquid, and spread thin upon wood, metal, paper, &c. so that the volatile menstruum may evaporate, the copal remains perfectly transparent, and forms one of the most beautiful and perfect varnishes that can well be conceived. The varnish thus formed is called *copal varnish*, from the chief ingredients in it. This varnish was first discovered in France, and was long known by the name of *vernis martin*. The method of preparing it is concealed; but different processes for dissolving copal in volatile menstrua have been from time to time made public.

According to the experiments of Thenard and Gay-Lussac, copal is composed of

Carbon	76.811
Oxygen	10.606
Hydrogen	12.583
	100.000

Lac,

10. *Lac.*—This is a substance deposited on different species of trees in the East Indies, by an insect called *chermes lacca*, constituting a kind of comb or nidus. It has been imported into Europe, and extensively used from time immemorial; but it is only of late years that correct information concerning it has been obtained. For what relates to the natural history of the insect, and the mode of forming the lac, we are indebted to Mr

Ker, Mr Saunders, and Dr Roxburgh. Though very often employed in the arts, it was neglected by chemists. Mr Hatchett has lately examined it with his usual address, and ascertained its composition and properties.

There are various kinds of lac distinguished in commerce. *Stick lac* is the substance in its natural state, encrusting small twigs. When broken off and boiled in water, it loses its red colour, and is called *seed lac*. When melted and reduced to the state of thin crust, it is called *shell lac*. Stick lac is of a deep red colour, and yields to water a substance which is used as a red dye. The other two varieties are brown.

Water dissolves the greatest part of the colouring matter of lac, which varies from 15 to ½ per cent. Alcohol dissolves the greatest part of the resin, which constitutes the chief ingredient in the composition of lac. Ether acts more feebly. Sulphuric acid dissolves and gradually chars lac; nitric acid dissolves, and then produces the same changes on it as on other resinous bodies. Muriatic and acetic acids likewise act as solvents. A solution of borax in water readily dissolves lac. The best proportions are 20 grains of borax, 100 grains of lac, and four ounces of water. This solution, mixed with lamp black, constitutes Indian ink, and may indeed be employed for many of the purposes of varnish. The fixed alkalies readily dissolve lac, but not the volatile. When placed on a hot iron it melts, and emits a thick smoke with an odour rather pleasant, leaving a spongy coal. When distilled, it yields water slightly acidulous, and a thick butyraceous oil. The gases emitted are a mixture of carbonic acid and carbureted hydrogen. Stick lack yields also some carbonate of ammonia; but the other two varieties none. The following Table exhibits the constituents of the different varieties of lac, according to the analysis of Mr Hatchett.

	Stick Lac.	Seed Lac.	Shell Lac.
Resin	68	88.5	90.9
Colouring matter	10	2.5	0.5
Wax	6	4.5	4.0
Gluten	5.5	2.0	2.8
Foreign bodies .	6.5		
Loss	4.0	2.5	1.8
	100	100	100

The resin is less brittle than those bodies usually are. The colouring matter possesses the properties of extractive; the wax is analogous to myrtle wax, and the gluten closely resembles the gluten of wheat.

Amber.

11. *Amber.*—This substance is undoubtedly of vegetable origin; and though it differs from resins in some of its properties, yet it agrees with them in so many others, that it may, without impropriety, be referred to them.

Amber is a brittle, light, hard substance, usually nearly transparent; sometimes nearly colourless, but commonly yellow or even deep brown. It has considerable lustre. Its specific gravity is 1.065. It is tasteless, and without smell, except when pounded or heated, when it emits a fragrant odour. When heated it softens; but, as far as is known, cannot be melted without losing some of its weight, and altering its appearance. In a strong heat it burns, leaving a small quantity of ashes, the nature of which has not yet been ascertained. Water has no action on it; but alcohol, by long digestion, dissolves about one eighth of the amber, and forms a coloured solution, which, when concentrated, becomes milky when mixed with water. The residuum of the amber is not acted on by alcohol. Though amber be roasted before the action of the alcohol, the tincture is still formed. Hence we learn that the resinous part of amber is not expelled by a melting heat.

The weaker acids have no action on amber. Sulphuric acid converts it into a black resinous mass. Nitric acid acts upon it; when assisted by heat, nitrous gas is emitted.

Amber varnish.

Neither fixed nor volatile oils have any action on amber unless it has been previously roasted or exposed to a melting heat. When thus treated, it combines with oils, and the solution forms *amber varnish*. The process recommended by Nystrom is this: Amber is to be spread on a flat-bottomed iron pan, and placed on an equal coal fire till it melt; it is then to be withdrawn, covered with a plate of copper and iron, and allowed to cool. If the process be properly conducted, the amber will have lost half of its weight. If the fire be too strong, the amber will be scorched and rendered useless. If it be too low, the amber will not melt, but be reduced to a brown crust, which answers well enough for a varnish, provided it be exposed to heat till it is reduced to one half of the original weight. One part of this roasted amber is to be mixed with three parts of the linseed oil (rendered drying by litharge and white vitriol,) and the mixture exposed to a gentle heat till the amber is dissolved: it is then to be withdrawn from the fire, and when nearly cold, four parts of oil of turpentine are to be added. The whole is then allowed to settle, and the clear portion is passed through a linen cloth.

SECT. XXIV. *Of Guaiacum.*

Guaiacum.

How obtained.

This substance is obtained from the *guaiacum officinale*, a tree which is a native of the West Indies, and yields a very hard heavy wood. The resin exudes spontaneously, and is also driven out artificially, by heating one end of the wood in billets previously bored longitudinally; the melted resin runs out at the extremity farthest from the fire. This substance has been used in medicine for a considerable time, having been originally recommended in venereal diseases. Nothing is known concerning its original introduction into Europe.

It was considered by chemists as a resin, till Mr Hatchett observed, that when treated with nitric acid it yielded products very different from those of the resinous bodies. This induced Mr William Brande to examine its chemical properties in detail.

Its properties.

Guaiacum is a solid substance, resembling a resin in appearance. Its colour differs considerably, being partly brownish, partly reddish, and partly greenish; and it always becomes green when left exposed to the light in the open air. It has a certain degree of transparency, and breaks with a vitreous fracture. When pounded it emits a pleasant balsamic smell, but has scarcely any taste, although when swallowed it excites a burning sensation in the throat. When heated it melts, and diffuses at the same time a pretty strong fragrant odour. Its specific gravity is 1.2289.

When guaiacum is digested in water, a portion of it is dissolved, the water acquiring a greenish brown colour, and a sweetish taste. The liquid, when evaporated, leaves a brown substance, which possesses the property of *extractive*.

Alcohol dissolves guaiacum with facility, and forms a deep brown-coloured solution. Water renders this solution milky by separating the resin. Muriatic acid throws down the guaiacum of an ash-grey, and sulphuric acid of a pale green colour. Acetic acid and the alkalies occasion no precipitate. Liquid oxymuriatic acid throws it down of a fine pale blue, which does not change when dried. Diluted nitric acid occasions no change at first; but after some hours the liquid becomes green, then blue, and at last brown, and at that period a brown-coloured precipitate falls down. If water be mixed with the liquid when it has assumed a green or a blue colour, green and blue precipitates may be respectively obtained.

Sulphuric ether does not act so powerfully on guaiacum as alcohol. The solution obtained by means of it, exhibits the same properties when treated with re-agents as that in alcohol.

The alkaline solutions, both pure and in the state of carbonates, dissolve guaiacum with facility. Two ounces of a saturated solution of potash dissolved about 65 grains of guaiacum; the same quantity of ammonia only 25 grains; or guaiacum dissolves in about 15 parts of potash, and 35 parts of ammonia.

Most of the acids act upon guaiacum with considerable energy.

Sulphuric acid dissolves it, and forms a deep red liquid, which deposites while fresh a lilac-coloured precipitate when mixed with water. When heat is applied, the guaiacum is charred.

Nitric acid dissolves guaiacum completely without the assistance of heat, and with a strong effervescence. When the solution is evaporated, it yields a very large quantity of oxalic acid. No artificial tannin appears to be formed, but rather a substance possessing the properties of extractive. Diluted nitric acid converts guaiacum into a brown substance, similar to the precipitate obtained by nitric acid from the alcoholic solution of guaiacum. This brown matter possesses the properties of a resin.

Muriatic acid acts but slightly, as the guaiacum soon melts into a blackish mass, which is not acted upon.

Composition.

When guaiacum is distilled, 100 parts of it yielded to Mr Brande the following products:

Acidulous water	5.5
Thick brown oil	24.5
Thin empyreumatic oil	30.0
Charcoal	30.5
Gases, consisting of carbonic acid and carbureted hydrogen	9.5
	100.0

The coal when incinerated left three grains of lime, but no alkaline substance.

SECT. XXV. *Of Balsams.*

Balsams.

The term *balsam* or *balm* was originally confined to a thick fragrant juice obtained from the *amyris gileadensis*, and afterwards applied by chemists to all substances which possess the same degree of consistence and a strong smell, whether natural or artificial. Bucquet restricted the term to those resinous-like substances which yield benzoic acid when heated. This new meaning of the word, which has been adopted by chemists in general, has introduced into the class of balsams several substances which were formerly considered as resins. The word *balsam* originally implied a substance possessing a certain degree of fluidity; but now there are two classes of balsams; the one fluid, and the other solid and brittle.

A balsam, then, is a substance which possesses the general properties of a resin; but which, when heated or digested in acids, yields a portion of benzoic acid. Chemists, in general, have considered them as combinations of a resin with benzoic acid; but Mr Hatchett has made it probable, that the acid is formed at the time of its separation.

Their properties.

They are insoluble in water; but when boiled in that liquid often give out a portion of benzoic acid. Alcohol and ether dissolve them readily. The strong acids likewise dissolve them; and during the solution a portion of benzoic acid is separated. Nitric acid, in some cases, evolves likewise traces of prussic acid. The alkalies act upon them nearly as on the resins. They may be divided into two classes; namely, *liquid* and *solid* balsams.

1. *Liquid Balsams.*

Liquid balsams, viz.

The liquid balsams at present known are four in number; namely,

1. Copaiva. 3. Peru.
2. Tolu. 4. Styrax.

Copaiva,

1. *Copaiva.* This balsam is obtained from the *copaifera officinalis*, a tree which grows in South America, and some of the West India Islands. It exudes from incisions made in the trunk of the tree. The juice thus obtained is transparent, of a yellowish colour, an agreeable smell, a pungent taste, at first of the consistence of oil, but it gradually becomes as thick as honey. Its specific gravity is 0.950. When mixed with water and distilled, there comes over with the water a very large quantity of volatile oil. The residuum consists of two substances; namely, the watery portion, and a greyish yellow substance, lying at the bottom of the vessel, which, on exposure to the air, dries, and becomes brittle and transparent. When heated it melts, and possesses the characters of a resin. When distilled it yielded a yellowish thick oil, some acidulous thick water, and a gas, one-sixth of which was carbonic acid, and the remainder seemed to possess the characters of olefiant gas. From these facts, which have been long known, it was concluded, that copaiva is a compound of a resin and a volatile oil, which passes over at a heat inferior to that of boiling water; but the experiments of Schonberg have rendered it much more probable, that the balsam is decomposed when distilled along with water, and that both the oil and resin are new products.

Whether this balsam yields benzoic acid has not been ascertained. Its properties are rather against the probability of its doing so. Indeed it bears a striking resemblance to turpentine in many respects, and ought, along with it, to constitute a class of bodies intermediate between volatile oils and resins, to which the name of *turpentines* might be given.

Balsam of tolu,

2. *Balsam of Tolu.* This substance is obtained from the *toluifera balsamum*, a tree which grows in South America. The balsam flows from incisions made in the bark. It comes to Europe in small gourd shells. It is of a reddish brown colour, and considerable consistence; and when exposed to the air, it becomes solid and brittle. Its smell is fragrant, and continues so even after the balsam has become thick by age. When distilled with water it yields very little volatile oil, but impregnates the water strongly with its taste and smell. A quantity of benzoic acid sublimes, if the distillation be continued.

Balsam of Peru,

3. *Balsam of Peru.* This substance is obtained from the *myroxylon peruiferum*, which grows in the warm parts of South America. The tree is full of resin, and the balsam is obtained by boiling the twigs in water. It has the consistency of honey, a brown colour, an agreeable smell, and a hot acrid taste. When boiled with water for some time, the liquid separated by the filter reddens vegetable blues, and deposits crystals of benzoic acid on cooling. The water contains no other substance. When

distilled with water, it yields a very small quantity of reddish limpid oil.

Styrax.

4. *Styrax.* This is a semifluid juice, said to be obtained from the *liquidambar styraciflua*, a tree which grows in Virginia, Mexico, and some other parts of America. It is prepared, according to Mr Petiver, in the island of Cobross in the Red Sea, from the bark of a tree called *rosa mallos* by the natives, and considered by botanists as the same with the American species. The bark of this tree is boiled in salt water to the consistence of bird-lime, and then put into casks. Its colour is greenish, its taste aromatic, and its smell agreeable. It is easily volatilized by heat. When treated with water, benzoic acid is dissolved. It is totally soluble in alcohol, except the impurities. When exposed to the air, it becomes harder, and absorbs oxygen. When distilled, it yields an acidulous water, having the odour of benzoic acid, a limpid colourless hot oil, a solid coloured oil, benzoic acid, and a mixture of carbonic acid and carbureted hydrogen. The charcoal is light, and contains some oil.

2. *Solid Balsams.*

Solid balsams, viz.

The solid balsams at present known are only three in number; namely,

1. Benzoin.
2. Storax.
3. Dragon's blood.

Benzoin,

1. **Benzoin.** This substance is the produce of the *styrax benzoe*, a tree which grows in Sumatra, &c. Benzoin is obtained from this tree by incision; a tree yielding three or four pounds. It is a solid brittle substance, sometimes in the form of yellowish white tears joined together by a brown substance, and sometimes in the form of a brown substance not unlike common rosin. It has a very agreeable smell, which is increased by heating the benzoin. It has little taste. Its specific gravity is 1.092.

Cold water has very little effect on benzoin, but boiling water takes up a portion of benzoic acid.

Alcohol dissolves it when assisted by a gentle heat, and forms a deep yellow solution inclining to reddish brown. When this solution is diluted with water, the benzoin precipitates in the form of a white powder.

Ether dissolves benzoin with facility, and the solution with re-agents exhibits the same phenomena as the alcoholic.

Nitric acid acts with violence on benzoin, and converts it into an orange-coloured mass. When assisted by heat, the acid dissolves the benzoin, and, as the solution cools, crystals of benzoic acid gradually separate.

Sulphuric acid dissolves benzoin, while benzoic acid sublimes; the solution is at first a deep red. By continuing the digestion, a portion of artificial tannin is formed, and the charcoal evolved amounts to 0.48 of the benzoin dissolved.

Acetic acid dissolves benzoin without the assistance of heat. When heat is applied, the solution, as it cools, becomes turbid, owing to the separation of benzoic acid.

Benzoin is dissolved, by a boiling lixivium of the fixed alkalies; a dark brown solution is formed, which becomes turbid after some days exposure to the air. Ammonia likewise dissolves benzoin sparingly.

When Mr Brande exposed 100 grains of benzoin in a retort to a heat gradually raised to redness, the products were,

Benzoic acid	9.0
Acidulous water	5.5
Butyraceous and empyreumatic oil	60.0
Charcoal	22.0
Carbureted hydrogen and carbonic acid	3.5
	100.0

Storax,

2. *Storax.* This is the most fragrant of all the balsams, and is obtained from the *styrax officinalis*, a tree which grows in the Levant, and it is said also in Italy. Sometimes it is in the state of red tears; and this is said to be the state in which it is obtained from the tree. But common storax is in large cakes; brittle, but soft to the touch, and of a reddish brown colour. This is more fragrant than the other sort, though it contains a considerable mixture of saw-dust. It dissolves in alcohol. When distilled with alcohol or with water, scarcely any oil is obtained. When distilled by the naked fire, it seems, from the experiments of Neumann, to yield the same products as benzoin.

Dragon's blood.

3. *Dragon's blood.* This is a brittle substance of a dark red colour, which comes from the East Indies. There are two sorts of it; one in small oval drops or tears of a fine deep red, which becomes crimson when the tears are reduced to powder; the other is in larger masses, some of which are pale red, and others dark. It is probably obtained from different kinds of trees; the *calamus draco* is said to furnish most of what comes from India. The *dracæna draco* and the *pterocarpus draco* are also said to furnish it.

Dragon's blood is brittle and tasteless, and has no sensible smell. Water does not act upon it, but alcohol dissolves the greatest part, leaving a whitish red substance, partially acted upon by water. The solution has a fine deep red colour, which stains marble, and the stain penetrates the deeper the hotter the marble is. It dissolves also in oils, and gives them a deep red colour. When heated, it melts, catches flame, and emits an acid fume similar to that of benzoic acid. When digested with lime, a portion of it becomes soluble in water, and it acquires a balsamic odour. On adding muriatic acid to the solution, a red resinous substance is precipitated, and slight traces of benzoic acid only become perceptible. Nitric acid acts upon it with energy, changes it to a deep yellow, a portion of benzoic acid is sublimed, and a brown mass remains soluble in water, and possessing the properties of artificial tannin.

SECT. XXVI. *Of Caoutchouc.*

Caoutchouc.

About the beginning of the 18th century, a substance called *caoutchouc* was brought as a curiosity from America. It was soft, wonderfully elastic, and very combustible. The pieces of it that came to Europe were usually in the shape of bottles, birds, &c. This substance is very much used in rubbing out the marks made upon paper by a black lead pencil, and therefore in this country it is often called *Indian rubber*.

How obtained.

It is now known, that there are at least two trees in South America from which caoutchouc may be obtained; the *hævea caoutchouc*, and the *jatropha elastica*; and it is exceedingly probable that it is extracted also from other species of *hævea* and *jatropha*. Several trees likewise which grow in the East Indies yield caoutchouc; the principal of these are, the *ficus indica*, the *artocarpus integrifolia*, and the *urceola elastica*.

When any of these plants are punctured, there exudes from it a milky juice, which, when exposed to the air, gradually lets fall a concrete substance, which is caoutchouc.

If oxymuriatic acid be poured into the milky juice, the caoutchouc precipitates immediately, and at the same time the acid loses its peculiar odour. This renders it probable that the formation of the caoutchouc is owing to its basis absorbing oxygen. If the milky juice be confined in a glass vessel containing common air, it gradually absorbs oxygen, and a pellicle of caoutchouc appears on its surface.

Its properties.

Caoutchouc, when pure, is of a white colour, and without either taste or smell. The blackish colour of the caoutchouc of commerce is owing to the method employed in drying it after it has been spread upon moulds. The usual way is to spread a thin coat of the milky juice upon the mould, and then to dry it by exposing it to smoke; afterwards another coat is spread on, which is dried in the same way. Thus the caoutchouc of commerce consists of numerous layers of pure caoutchouc alternating with as many layers of soot.

Caoutchouc is soft and pliable like leather. It is exceedingly elastic and adhesive, so that it may be forcibly stretched out much beyond its usual length, and instantly recover its former bulk when the force is withdrawn. It cannot be broken without very considerable force. Its specific gravity is 0.9335.

Caoutchouc is not altered by exposure to the air; it is perfectly insoluble in water; but if boiled for some time, its edges become somewhat transparent, owing undoubtedly to the water carrying off the soot; and so soft, that when two of them are pressed and kept together for some time, they adhere as closely as they formed one piece. By this contrivance pieces of caoutchouc may be soldered together, and thus made to assume whatever shape we please.

Caoutchouc is insoluble in alcohol. This property was discovered very early, and fully confirmed by the experiments of Mr Macquer. The alcohol, however, renders it colourless.

Caoutchouc is soluble in ether. This property was first pointed out by Macquer. Berniard, on the contrary, found that caoutchouc was scarcely soluble at all in sulphuric ether, which was the ether used by Macquer, and that even nitric ether was but an imperfect solvent. The difference in the results of these two chemists was very singular; both were remarkable for their accuracy, and both were too well acquainted with the subject to be easily misled. The matter was first cleared up by Mr Cavallo. He found that ether, when newly prepared, seldom or never dissolved caoutchouc completely; but if the precaution was taken to wash the ether previously in water, it afterwards dissolved caoutchouc with facility.

When the ether is evaporated, the caoutchouc is obtained unaltered. Caoutchouc, therefore, dissolved in ether, may be employed to make instruments of different kinds, just as the milky juice of the *hævea*; but this method would be a great deal too expensive for common use.

Caoutchouc is soluble in volatile oils; but, in general, when these oils are evaporated, it remains somewhat glutinous, and therefore is scarcely proper for those uses to which, before its solution, it was so admirably adapted.

The acids act but feebly upon caoutchouc. Sulphuric acid, even after a long digestion, only chars it superficially. When treated with nitric acid, there came over azotic gas, carbonic acid gas, prussic acid gas; and oxalic acid is said to be formed. Muriatic acid does not affect it. The other acids have not been tried.

Fabroni has discovered, that rectified petroleum dissolves it, and leaves it unaltered when evaporated.

When exposed to heat it readily melts; but it never afterwards recovers its properties, but continues always of the consistence of tar. It burns very readily with a bright flame, and diffuses a fetid odour. In those countries where it is produced, it is often used by way of candle.

When distilled, it gives out ammonia. It is evident from this, and from the effect of sulphuric and nitric acid upon it, that it is composed of carbon, hydrogen, azote, and oxygen; but the manner in which they are combined is unknown.

Sect. XXVII. *Of Gum Resins.*

Gum resins.

This class of vegetable substances has been long distinguished by physicians and apothecaries. It contains many active substances much employed in medicine; and they certainly possess a sufficient number of peculiar properties to entitle them to be ranked apart. Unfortunately these substances have not yet attracted much of the attention of chemists. Their properties and constituents, of course, are but imperfectly ascertained.

They are usually opake, or at least their transparency is inferior to that of the resins. They are always solid, and most commonly brittle, and have sometimes a fatty appearance.

When heated, they do not melt as the resins do; neither are they so combustible. Heat, however, commonly softens them, and causes them to swell. They burn with a flame.

They have almost always a strong smell, which in several instances is alliaceous. Their taste also is often acrid, and always much stronger than that of the resins.

They are partially soluble in water; but the solution is always opake, and usually milky.

Alcohol dissolves only a portion of them. The solution is transparent; but when diluted with water it becomes milky; yet no precipitate falls, nor is any thing obtained by filtering the solution.

Vinegar and wine likewise dissolve them partially; and the solution, like the aqueous, is opaque or milky.

According to Hermbstadt, they are insoluble in sulphuric ether.

The action of alkalies on them has been examined only by Mr Hatchett. All of them tried by that celebrated chemist, dissolved readily in alkaline solutions, when assisted by heat. We may therefore consider them as soluble in alkalies like resins.

Nitric acid acts upon them with energy; converting them first into a brittle mass, and then, with the assistance of heat, dissolving them.

Their specific gravity is usually greater than that of the resins.

Their other properties still continue unknown. They all either exude spontaneously from plants, or are obtained by incisions. At first they seem to be in a liquid state; but they gradually harden when exposed to the air and weather.

The gum resins which have been hitherto applied to any useful purpose are the following:—

Galbanum.

1. *Galbanum.* It is obtained from the *bubon galbanum*, a perennial plant, and a native of Africa. When this plant is cut across a little above the root, a milky juice flows out, which soon hardens and constitutes galbanum. It comes to this country from the Levant, in small pieces, composed of tears, agglutinated together, of a yellowish or white colour. Its taste is acrid and bitter, and its smell peculiar. Water, vinegar, and wine, dissolve part of it, but the solution is milky. Alcohol dissolves about three-fifths.

Ammoniac. 2. *Ammoniac.*—This substance is brought from the East Indies. Nothing certain is known concerning the plant which yields it; though from analogy it has been suspected to be a species of *ferula*. It is in small pieces, agglutinated together, and has a yellowish white colour. Its smell is somewhat like that of galbanum, but more pleasant. Its taste is a nauseous sweet, mixed with bitter. It does not melt. Water dissolves a portion of it; the solution is milky, but gradually lets fall a resinous portion. More than one half is soluble in alcohol. This portion is a resin.

According to the analysis of Braconnot, ammonia is composed of the following ingredients:

70.0	resin
18.4	gum
4.4	glutinous matter
6.0	water
1.2	loss
100.0	

Olibanum. 3. *Olibanum.*—This substance is obtained from the *Boswallia thurifera*, and is chiefly collected in India. It is the frankincense of the ancients. It is in transparent brittle masses about the size of a chesnut. Its colour is yellow. It has a bitterish nauseous taste; and when burnt diffuses an agreeable odour. Alcohol dissolves three fourths of it, and water about three-eighths.

Asafœtida. 4. *Asafœtida.*—This substance is obtained from the *ferula asafœtida*, a perennial plant, which is a native of Persia. When the plant is about four years old, its roots are dug up and cleaned. Their extremity being then cut off, a milky juice exudes, which is collected. Then another portion is cut off, and more juice exudes. This is continued till the roots are exhausted. The juice thus collected soon hardens and constitutes *asafœtida*. It comes to Europe in small grains of different colours, whitish, reddish, violet, brown. It is pretty hard, but brittle. Its taste is acrid and bitter; its smell strongly alliaceous and fetid. Alcohol dissolves about three-fourths of this substance; and water takes up nearly one-fourth if applied before the spirit.

Scammony. 5. *Scammony.*—This substance is obtained from the *convolvulus scammonia*, a climbing plant which grows in Syria. The roots, when cut, yield a milky juice. This, when collected and allowed to harden, constitutes scammony. Colour dark grey or black. Smell peculiar and nauseous: taste bitter and acrid. With water it forms a greenish-coloured opaque liquid. Alcohol dissolves the greatest part of it. It is usually mixed with the expressed juice of the root, and frequently also with other impurities, which alter its appearance. In medicine it operates as a strong cathartic.

Opoponax. 6. *Opoponax.*—This substance is obtained from the *pastinaca opoponax*, a plant which is a native of the countries round the Levant. The gum resin, like most others, is obtained by wounding the roots of the plant. The milky juice, when dried in the sun, constitutes the opoponax. It is in lumps of a reddish yellow colour, and white within. Smell peculiar. Taste bitter and acrid. With water it forms a milky solution, and about one-half of it dissolves. Alcohol acts but feebly.

Gamboge. 7. *Gamboge* or *Gumgutt.*—This substance is obtained from the *stalagmitis gambogioides*, a tree which grows wild in the East Indies. In Siam it is obtained in drops by wounding the shoots; in Ceylon it exudes from wounds in the bark. It is brought to Europe in large cakes. Its colour is yellow; it is opaque, brittle, and breaks vitreous. It has no smell, and very little taste. With water it forms a yellow turbid liquid. Alcohol dissolves it almost completely; and when mixed with water becomes turbid, unless the solution contains ammonia.

Braconnot analyzed it, and found it composed of one part of a gum which possessed the properties of cherry tree gum, and four parts of a reddish brittle resin, which possessed the characteristic properties of the resins.

Myrrh. 8. *Myrrh.*—The plant from which this substance is obtained is unknown. According to Bruce, it belongs to the genus of *mimosa*. It grows in Abyssinia and Arabia. It is in the form of tears. Colour reddish yellow; when pure somewhat transparent, but it is often opake. Odour peculiar. Taste bitter and aromatic. Does not melt when heated, and burns with difficulty.

From the analysis of Braconnot it appears that myrrh is composed of about

23	resin
77	gum
100	

The resin is reddish, has a bitter taste, and the peculiar odour of myrrh. The gum differs in its properties from every other gummy substance hitherto examined. It has a dark brown colour; is at first soluble in water, but by boiling the liquid, or by exposing the gum to heat, it requires cohesive properties, and becomes insoluble in water. When distilled it yields ammonia, and when dissolved in nitric acid, azotic gas is disengaged.

It deserves attention, that the gum resins, when subjected to destructive distillation, yield all of them a portion of ammonia; a proof that they all contain azote. In this respect they agree with gum and extractive.

SECT. XXVIII. *Of Cotton.*

Cotton. Cotton is a soft down which envelopes the seeds of various plants, especially the different species of *gossypium*, from which the cotton of commerce is procured. These plants are natives of warm climates; grow wild in Asia, Africa, and America, within the tropics; and are cultivated in the East and West Indies.

Though no correct chemical investigation of the properties of cotton has hitherto been made, yet as its obvious qualities distinguish it sufficiently from every other vegetable substance, we must consider it as a peculiar vegetable principle; and it has been introduced here, in hopes that some person or other will be induced to examine its nature in detail. The following are the particulars at present known.

Properties at present known. This substance is in threads differing in length and fineness. No asperities can be discovered on the surface of these threads; but if Lewenhoeck's microscopical observations are to be trusted, they are all triangular, and have three sharp edges. Cotton differs considerably in colour; but when *bleached* it becomes of a fine white.

Cotton is tasteless and destitute of smell. It is completely insoluble in water, alcohol, ether, and oils, and in all the vegetable acids.

The diluted alkaline leys have no perceptible action on cotton; but when very strong they dissolve it if assisted by a sufficient degree of heat. The new products obtained by this solution have not been examined.

Cotton combines readily with tannin, and forms a yellow or brown compound. Hence the infusion of galls, and other astringent substances, is often used as a mordant for cotton.

Nitric acid decomposes cotton when assisted by heat, and oxalic acid is formed; the other products have not been examined. Sulphuric acid likewise chars it. Oxymuriatic acid gas bleaches it, and probably alters and dissolves it when applied in a concentrated state.

Cotton is extremely combustible, and burns with a clear lively flame. The ashes left behind, according to Neumann, contain some potash. When distilled, it yields a great portion of acidulous water, and a small quantity of oil, but no ammonia.

SECT. XXIX. *Of Suber.*

Suber.

This name has been introduced into chemistry by Fourcroy, to denote the outer bark of the *quercus suber*, or the common cork; a substance which possesses properties different from all other vegetable bodies.

Its properties.

It is exceedingly light, soft, and elastic; very combustible, burning with a bright white flame, and leaving a light black bulky charcoal; and when distilled, it yields a little ammonia.

When digested in water, a yellowish coloured solution is obtained, seemingly containing extractive, as nearly the same proportion is taken up by alcohol. Sulphuric acid readily chars it. Nitric acid gives it a yellow colour, corrodes, dissolves, and decomposes it; converting it partly into suberic acid, partly into a substance resembling wax, partly into artificial tannin, and partly into a kind of starchy matter.

SECT. XXX. *Of Wood.*

Wood.

All trees, and most other plants, contain a particular substance, well known by the name of *wood*. If a piece of wood be well dried, and digested, first in a sufficient quantity of water, and then of alcohol, to extract from it all the substances soluble in these liquids, there remains only behind the *woody fibre*.

Its properties.

This substance, which constitutes the basis of wood, is composed of longitudinal fibres, and is easily subdivided into a number of smaller fibres. It is somewhat transparent; is perfectly tasteless; has no smell; and is not altered by exposure to the atmosphere.

It is insoluble in water and in alcohol. The fixed alkalies, when assisted by heat, give it a deep brown colour, render it soft, and decompose it. A weak alkaline solution dissolves it without alteration; and it may be thrown down again by means of an acid. By this property we are enabled to separate wood from most of the other vegetable principles, as few of them are soluble in weak alkaline leys.

When heated, it blackens without melting or frothing up, and exhales a disagreeable acrid fume, and leaves a charcoal which retains exactly the form of the original mass. When distilled in a retort, it yields an acid liquor of a peculiar taste and smell, distinguished by the name of pyrolignous, and formerly considered as a distinct acid; but Fourcroy and Vauquelin have lately ascertained that it is merely the acetic acid combined with an empyreumatic oil.

Composition of oak.

Thenard and Gay-Lussac found the constituents of oak,

Oxygen, - - -	41.78
Carbon, - - -	52.53
Hydrogen, - - -	5.69
	100

Of beech.

The constituents of beech they found to be

Oxygen, - - -	42.73
Carbon, - - -	51,45
Hydrogen, - - -	5.82
	100

SECT. XXXI. *Of Alkalies.*

Alkalies found in plants.

The only alkalies found in plants are potash and soda. Ammonia may indeed be obtained by distilling many vegetable substances, but it is produced during the operation. One or other of these alkalies is found in every plant which has hitherto been examined. The quantity indeed is usually very small. From the experiments of Vauquelin, it is probable that the alkalies are combined in plants with acetic and carbonic acids.

Potash.

1. Potash is found in almost all plants which grow at a distance from the sea. It may be extracted by burning the vegetable, washing the ashes in water, filtrating the water, and evaporating it to dryness. It is in this manner that all the potash of commerce is procured.

In general, three times as much ashes are obtained from shrubs, and five times as much from herbs, as from trees. Equal weights of the branches of trees produce more ashes than the trunk, and the leaves more than the branches. Herbs arrived at maturity produce more ashes than at any other time. Green vegetables produce more ashes than dry.

Soda.

2. Soda is found in almost all the plants which grow in the sea, and in many of those which grow on the shore. In general, the quantity of soda which plants contain bears a much greater proportion to their weight than the potash does which is found in inland vegetables. 100 parts of the *salsola soda*, for instance, yield 19.921 of ashes; and these contain 1.992 parts of soda; some of which, however, is combined with muriatic acid. The plants from which the greater part of the soda, or *barilha* as it is called, which is imported from Spain, is extracted, are the *salsola sativa* and *vermiculata*.

SECT. XXXII. *Of Earths.*

Earths found in plants.

The only earths hitherto found in plants are the four following: *lime, silica, magnesia, alumina.*

Lime.

1. Lime is usually the most abundant of the earths of plants, and the most generally diffused over the vegetable kingdom. Indeed it is a very uncommon thing to find a plant entirely destitute of lime: salsola soda is almost the only one in which we know for certain that this earth does not exist.

Silica.

2. Silica exists also in many plants, particularly in grasses and equisetums. Mr Davy has ascertained that it forms a part of the epidermis, or outer bark of these plants; and that in some of them almost the whole epidermis is silica.

Magnesia.

3. Magnesia does not exist so generally in the vegetable kingdom as the two preceding earths. It has been found, however, in considerable quantities in several sea plants, especially fuci; but the salsola soda contains a greater proportion of magnesia than any plant hitherto examined. Mr Vauquelin found that 100 parts of it contained 17.929 of that earth.

Alumina.

4. Alumina has only been found in very small quantities in plants.

The following Table exhibits the quantity of earths and metallic oxides in grains, obtained by Schræder from 32 ounces of the seeds of the following kinds of corn; wheat (*triticum hybernum*), rye (*secale cereale*), barley (*hordeum vulgare*), oats (*avena sativa*), and likewise from the same quantity of rye straw.

	Wheat.	Rye.	Barley.	Oats.	Rye Straw.
Silica	13.2	15.6	66.7	144.2	152
Carbonate of lime . .	12.6	13.4	24.8	33.75	46.2
Carbonate of magnesia	13.4	14.2	25.3	33.9	28.2
Alumina	0.6	1.4	4.2	4.5	3.2
Oxide of manganese .	5.0	3.2	6.7	6.95	6.8
Oxide of iron	2.5	0.9	3.8	4.5	2.4
	47.3	48.7	131.5	227.8	328.8

Sect. XXXIII. *Of Metals.*

Metals found in ashes of vegetables.

Several metallic substances have also been found in the ashes of vegetables, but their quantity is exceedingly small; so small, indeed, that without very delicate experiments their presence cannot even be detected.

The metals hitherto discovered are iron, which is by far the most common, manganese, and, if we believe some chemists, gold.

Iron.

1. Iron has been found in many plants; the ashes of salsola contain a considerable quantity of it.

Manganese.

2. Scheele first detected manganese in vegetables. Proust found it in the ashes of the pine, calendula, vine, green oak, and fig-tree.

Gold.

3. With respect to the minute portion of gold extracted from the ashes of plants by Kunkel, Sage, &c. it is probable that it proceeded rather from the lead which they employed in their processes than from the ashes.

BOOK V.

OF ANIMALS.

Of animals.

When we compare animals and vegetables together, each in their most perfect state, nothing can be easier than to distinguish them. The plant is confined to a particular spot, and exhibits no mark of consciousness or intelligence: the animal, on the contrary, can remove at pleasure from one place to another, is possessed of consciousness, and a high degree of intelligence. But on approaching the contiguous extremities of the animal and vegetable kingdom, these striking differences gradually disappear; the objects acquire a greater degree of resemblance; and at last approach each other so nearly, that it is scarcely possible to decide whether some of those species which are situated on the very boundary, belong to the animal or vegetable kingdom.

To draw a line of distinction, then, between animals and vegetables, would be a very difficult task: but it is not necessary at present to attempt it; for almost the only animals whose bodies have been hitherto examined with any degree of chemical accuracy, belong to the most perfect classes, and consequently are in no danger of being confounded with plants. Indeed, the greater number of facts which we have to relate apply only to the human body, and to those of a few domestic animals. The task of analysing all animal bodies is immense, and must be the work of ages of indefatigable industry.

This part of the subject naturally divides itself into two Chapters. In the first Chapter, we shall give an account of the different ingredients hitherto found in animals, such of them at least as have been examined with any degree of accuracy; and, in the second, we shall treat of the different members of which animal bodies are composed, which must consist each of various combinations of the ingredients described in the first Chapter.

Chap. I.

Of Animal Substances.

Animal substances.

The substances which have been hitherto detected in the animal kingdom, and of which the different parts of animals, as far as these parts have been analysed, are found to be composed, may be arranged under the following heads:

1. Gelatine.	8. Resins.
2. Albumen.	9. Sulphur.
3. Mucus.	10. Phosphorus.
4. Fibrin.	11. Acids.
5. Urea.	12. Alkalies.
6. Saccharine matter.	13. Earths.
7. Oils.	14. Metals.

These shall form the subject of the following Sections.

Sect. I. *Of Gelatine.*

Gelatine.

If a piece of the fresh skin of an animal, an ox for instance, after the hair and every impurity is carefully separated, be washed repeatedly in cold water till the liquid ceases to be coloured, or to abstract any thing; if the skin, thus purified, be put into a quantity of pure water, and boiled for some time, part of it will be dissolved. Let the decoction be slowly evaporated till it is reduced to a small quantity, and then put aside to cool. When cold, it will be found to have assumed a solid form, and to resemble precisely that tremulous substance well known to every body under the name of *jelly.* This is the substance called in chemistry *gelatine.* If the evaporation be still farther continued, by exposing the jelly to dry air, it becomes hard, semitransparent, breaks with a glassy fracture, and is, in short, the substance so much employed in different arts under the name of *glue.* Gelatine, then, is precisely the same with glue; only that it must be supposed always free from those impurities with which glue is so often contaminated.

How obtained.

Its properties.

Gelatine is semitransparent, and colourless when pure. Its consistency and hardness vary considerably. The best kinds are very hard, brittle, and break with a glassy fracture. Its taste is insipid, and it has no smell.

When thrown into water it swells very much, but does not readily dissolve; and when taken out, it is soft and gelatinous; but when allowed to dry, it recovers its former appearance. If it be put in this gelatinous state into warm water, it very soon dissolves, and forms a solution of an opal colour, and the more opake according to the quantity of gelatine which it contains. Tremulous gelatine dissolves in a very small portion of hot water; but as the solution cools, it gelatinizes afresh. If this solution, as soon as it assumes the tremulous form, be mixed with cold water and shaken, a complete solution takes place.

Dry gelatine undergoes no change when kept; but in the gelatinous state, or when dissolved in water, it very soon putrefies; an acid makes its appearance in the first place, (probably the acetic,) a fetid odour is exhaled, and afterwards ammonia is formed.

Acids dissolve gelatine with facility, even when diluted, especially when assisted by heat; but we are still ignorant of the changes produced upon it by these agents, except by nitric acid. When this acid is digested on it, a small quantity of azotic gas is disengaged, then abundance of nitrous gas; the gelatine is dissolved, except an oily matter which appears on the surface, and converted partly into oxalic and malic acids.

Alkalies dissolve gelatine with facility, especially when assisted by heat; but the solution does not possess the properties of soap.

None of the earths seem to combine with gelatine; at least they do not precipitate it from its solution in water.

The metals, in their pure state, have no effect upon gelatine; but several of the metallic oxides, when agitated in a solution of gelatine, have the property of depriving the water of the greatest part of that body, with which they form an insoluble compound. Several of the metallic salts likewise precipitate gelatine from water.

Gelatine is insoluble in alcohol. When alcohol is mixed with a solution of gelatine, the mixture becomes milky; but becomes again transparent when agitated, unless the solution be concentrated, and the quantity of alcohol considerable. Gelatine is most probably equally insoluble in ether; though I believe the experiment has not been tried.

When the solution of tannin is dropt into gelatine, a copious white precipitate appears, which soon forms an elastic adhesive mass not unlike vegetable gluten. This precipitate is composed of gelatine and tannin; it soon dries in the open air, and forms a brittle resinous-like substance, insoluble in water, capable of resisting the greater number of chemical agents, and not susceptible of putrefaction.

Gelatine does not, properly speaking, combine with oils, but it renders them miscible with water, and forms a kind of emulsion.

From the effects of different re-agents on gelatine, and from the decomposition which it undergoes when heated, we see that it contains carbon, hydrogen, azote, and oxygen. The phosphate of lime, and the traces of soda, which it always yields, are most likely only held in solution by it. The constituents, according to the experiments of Thenard and Gay-Lussac, was as follows:

Composition.

Carbon,	67.881
Oxygen,	27.207
Hydrogen,	7.914
Azote,	16.998
	100

Sect. II. *Of Albumen.*

Albumen.

The eggs of fowls contain two very different substances: a yellow oily-like matter, called the *yolk;* and a colourless glossy viscid liquid, distinguished by the name of *white.* This last is the substance which chemists have agreed to denominate *albumen.* The white of an egg, however, is not pure albumen. It contains also some mucus, soda, and sulphur: but as albumen is never found perfectly pure, and as no method is known of separating it, without at the same time altering the properties of the albumen, chemists are obliged to examine it while in combination with these bodies.

Its properties.

Albumen dissolves readily in water, and the solution has the property of giving a green colour to vegetable blues, in consequence of the soda which it contains. When albumen is heated to the temperature of 165°, it *coagulates* into a white solid mass; the consistency of which, when other things are equal, depends, in some measure, on the time during which the heat was applied. The coagulated mass has precisely the same weight that it had while fluid. This property of coagulating when heated is characteristic of albumen, and distinguishes it from other bodies.

The taste of coagulated albumen is quite different from that of liquid albumen: its appearance, too, and its properties, are entirely changed; for it is no longer soluble, as before, either in hot or in cold water.

The coagulation of albumen takes place even though air be completely excluded; and even when air is present, there is no absorption of it, nor does albumen in coagulating change its volume. Acids have the property of coagulating albumen, as Scheele ascertained. Alcohol also produces, in some measure, the same effect. *Heat,* then, *acids* and *alcohol,* are the agents which may be employed to coagulate albumen.

It is remarkable, that if albumen be diluted with a sufficient quantity of water, it can no longer be coagulated by any of these agents.

We see, therefore, that albumen ceases to coagulate whenever its particles are separated from each other beyond a certain distance. That no other change is produced, appears evident from this circumstance, that whenever the watery solution of albumen is sufficiently concentrated by evaporation, coagulation takes place, upon the application of the proper agents, precisely as formerly.

It does not appear that the distance of the particles of albumen is changed by coagulation; for coagulated albumen occupies precisely the same sensible space as liquid albumen.

Albumen, then, is capable of existing in two states; the one before it has been coagulated, and the other after it has undergone coagulation. Its properties are very different in each. It will be proper therefore to consider them separately.

Albumen, in its natural state, or uncoagulated, is a glary liquid, having little taste and no smell. When dried spontaneously, or in a low heat, it becomes a brittle transparent glassy-like substance; which, when spread thin upon surfaces, forms a varnish, and is accordingly employed by bookbinders for that purpose. When thus dried, it has a considerable resemblance to gum arabic, to which also its taste is similar. The white of an egg loses about four-fifths of its weight in drying. It is still soluble in water, and forms the same glary liquid as before.

From the experiments of Dr Bostock, it appears, that when one part of this dry albumen is dissolved in nine parts of water, the solution becomes perfectly solid when coagulated by heat; but if the albumen amounts only to $\frac{1}{11}$th of the liquid, then, though coagulation takes place, the liquid does not become perfectly solid, but may be poured from one vessel to another.

When one grain of albumen is dissolved in 1000 grains of water, the solution becomes cloudy when heated.

Uncoagulated albumen.

I. Uncoagulated albumen soon putrefies, unless it be dried; in which state it does not undergo any change. It putrefies more readily when dissolved in a large quantity of water, than when concentrated. The smell of the white of egg, allowed to run into putrefaction, resembles that of *pus*.

It is insoluble in alcohol and ether, which immediately coagulate it, unless it be mixed with a very great proportion of water; in which case even acids have no effect.

When acids are poured upon it, coagulation takes place equally; but several of them have the property of dissolving it again when assisted by heat. This at least is the case with sulphuric acid. The solution is of a green colour, and does not soon blacken even when boiled. It is the case also with nitric acid, and probably also with muriatic acid. Nitric acid first disengages some azotic gas; then the albumen is gradually dissolved, nitrous gas emitted, oxalic and malic acids formed, and a thick oily matter makes its appearance on the surface.

None of the earths form insoluble compounds with albumen; in this respect they resemble the alkalies. The case is different with the metallic oxides.

Every metal tried, except cobalt, occasions a precipitate; but no precipitate ever appears when the oxide is held in solution by an alkali or earth. The effect of the metallic salts on albumen forms a striking contrast with their effect on gelatine.

From the experiments of Dr Bostock, it appears that a drop of the saturated solution of oxymuriate of mercury, let fall into water containing $\frac{1}{1000}$th part of its weight of albumen, produces an evident milkiness, and a curdy precipitate falls. It is therefore a very delicate test of the presence of albumen in animal fluids.

If a solution of tannin be poured into an aqueous solution of uncoagulated albumen, it forms with it a very copious yellow precipitate of the consistence of pitch, and insoluble in water. This precipitate is a combination of tannin and albumen. When dry it is brittle, like over-tanned leather, and is not susceptible of putrefaction. This property which albumen has of precipitating with tannin was discovered by Seguin.

The infusion of galls is by no means so delicate a test of the presence of albumen as of gelatine. When an infusion of galls, containing 2½ per cent. of solid matter, and water holding $\frac{1}{1000}$th of albumen in solution, are mixed in equal quantities, no effect is produced at first, but after some time a precipitating matter appears, and slowly subsides.

Coagulated albumen.

II. When albumen is coagulated either by heat, alcohol, or acids, it is an opaque substance of a pearl white colour, tough, and of a sweetish mucilaginous taste. It is no longer soluble in water, and is not nearly so susceptible of decomposition as uncoagulated albumen. Mr Hatchett kept it for a month under water, and yet it did not become putrid.

When this substance was digested for some hours in water, it gradually softened, and became white and opake like newly coagulated albumen. When water is made to act upon it long, a small portion of it is taken up. The watery liquid is not precipitated by the infusion of tan; but nitromuriate of tin occasions a faint cloud.

According to Scheele, the mineral acids, when greatly diluted with water, dissolve a portion of coagulated albumen, which is thrown down again by the same acids concentrated.

When coagulated albumen is steeped in diluted nitric acid, the acid in about four weeks begins to acquire a yellow tinge, which becomes gradually deeper; but the albumen, though it becomes more opake, is not dissolved. The yellow acid, when saturated with ammonia, becomes of a deep orange colour, but does not let fall any precipitate. When the albumen, thus treated, is immersed in ammonia, the liquid assumes a deep orange colour, inclining to blood-red. The albumen is slowly dissolved, and the solution has a deep yellowish brown colour. If the albumen, after being steeped in nitric acid, be washed and then boiled in water, it is dissolved, and forms a pale yellow liquid, which gelatinises when properly concentrated. If the gelatinous mass be again dissolved in boiling water, the solution is precipitated by tan and by nitro muriate of tin. Hence we see that nitric acid has the property of converting coagulated albumen into gelatine.

Concentrated nitric acid dissolves coagulated albumen with effervescence, especially when assisted by heat. It becomes orange brown when mixed with ammonia, but no precipitate falls.

It is readily dissolved by boiling lixivium of potash, ammonia is disengaged, and an animal soap is formed. This soap, when dissolved in water, and mixed with acetic or muriatic acids, lets fall a precipitate which is of a saponaceous nature. When heated gently, some oil flows from it, and a brownish viscid substance remains. The alkalies, when diluted, and not assisted by heat, act upon it slowly and imperfectly.

These properties indicate sufficiently that coagulated albumen is a very different substance from uncoagulated albumen.

III. From the effects of nitric acid on albumen; and its products, when subjected to destructive distillation, it has been concluded that it consists of carbon, hydrogen, azote, and oxygen.

Composition.

According to the experiments of Thenard and Gay-Lussac, its constituents are as follows:

Carbon, ...	52.883
Oxygen, ...	23.872
Hydrogen, ...	7.540
Azote, ...	15.705
	100

Mr Hatchett has rendered it very probable that it is the first of the soft part of animals that is formed, and that all the other soft parts are formed from it.

SECT. III. *Of Mucus.*

Mucus.

No word in chemistry has been used with less precision than *mucus*. Too many experimenters have made it serve as a common name for every animal substance which cannot be referred to any other class. Dr Bostock, in his excellent papers on the *Analysis of Animal Fluids*, has endeavoured to fix the meaning of the word, by ascertaining the properties of pure mucus. Fourcroy and Vauquelin have lately written an elaborate paper on the same subject.

How obtained.

From Bostock's experiments it appears, that if the solid matter obtained by evaporating saliva to dryness be re-dissolved in water and filtered, the solution will contain very little except mucus. He obtained mucus, also, by macerating an oyster in water, and evaporating the liquid. Mucus, thus obtained, possesses the following properties:

Its properties.

1. It has much the appearance of gum arabic, excepting that, in general, it is rather more opaque; like it, it has little taste, dissolves readily in water, and forms an adhesive solution.

2. When evaporated to dryness, it is transparent, inelastic, and has much the appearance of gum. It is insoluble in water, but dissolves readily in all the acids, though very much diluted.

3. It does not dissolve in alcohol, nor in ether.

4. It does not coagulate when heated; nor when con-

centrated by evaporation does its solution assume the form of a jelly.

5. It is not precipitated by the oxymuriate of mercury, nor by the infusion of galls.

6. The acetate of lead occasions a copious white precipitate when dropt into solutions containing mucus; the superacetate produces a much less striking effect.

7. Nitrate of silver likewise occasions a precipitate in solutions containing mucus.

8. When heated, it assumes the appearance of horn, and when distilled it yields the common products of animal substances. According to Fourcroy and Vauquelin, horn, nails, hair, feathers, the epidermis, and the scales which form on the skin, consist chiefly of mucus.

Many of the substances called *mucus* have the property of absorbing oxygen, and of becoming by that means insoluble in water. They resemble vegetable extractive matter in this respect.

Sect. IV. *Fibrin.*

Fibrin.

How obtained.

If a quantity of blood, newly drawn from an animal, be allowed to remain at rest for some time, a thick red clot gradually forms in it, and subsides. Separate this clot from the rest of the blood, put it into a linen cloth, and wash it repeatedly in water till it ceases to give out any colour or taste to the liquid; the substance which remains after this process is denominated *fibrin*. It has been long known to physicians under the name of the *fibrous part of the blood*, but has not till lately been accurately described.

It may be procured also from the muscles of animals. Mr Hatchett, to whom we are indebted for a very interesting set of experiments on this substance, cut a quantity of lean beef into small pieces, and macerated it in water for 15 days, changing the water every day, and subjecting the beef to pressure at the same time, in order to squeeze out the water. As the weather was cold, it gave no signs of putrefaction during this process. The shreds of muscle, which amounted to about three pounds, were now boiled for five hours every day, for three weeks, in six quarts of fresh water, which was regularly changed every day. The fibrous part was now pressed, and dried by the heat of a water bath. After this treatment it might be considered as fibrin nearly as pure as it can be obtained.

Its properties.

Fibrin is of a white colour, has no taste nor smell, and is not soluble in water nor in alcohol. When newly extracted from blood, it is soft and elastic, and resembles very much the gluten of vegetables. Its colour deepens very much in drying. That which is extracted from muscle by boiling and maceration has a certain degree of transparency, and is not ductile but brittle. Its colour does not deepen nearly so much as the fibrin from blood.

It undergoes no change though kept exposed to the action of air; neither does it alter speedily though kept covered with water. Mr Hatchett kept a quantity of the fibrin which he had prepared from beef moistened with water during the whole month of April; it acquired a musty but not a putrid smell, neither were the fibres reduced to a pulpy mass. Even when kept two months under water, it neither became putrid, nor was converted into the fatty matter obtained by macerating recent muscle.

When fibrin is exposed to heat, it contracts very suddenly, and moves like a bit of horn, exhaling at the same time the smell of burning feathers. In a stronger heat it melts. When exposed to destructive distillation, it yields water, carbonate of ammonia, a thick heavy fetid oil, traces of acetic acid, carbonic acid, and carbureted hydrogen gas.

Acids dissolve fibrin with considerable facility. Sulphuric acid gives it a deep brown colour; charcoal is precipitated, and acetic acid formed. Muriatic acid dissolves it, and forms with it a green-coloured jelly. The acetic, citric, oxalic, and tartaric acids also dissolve it by the assistance of heat; and the solutions, when concentrated, assume the appearance of jelly. Alkalies precipitate the fibrin from acids in flakes, soluble in hot water, and resembling gelatine in its properties.

Diluted nitric acid occasions the separation of a good deal of azotic gas, as was first observed by Berthollet. Mr Hatchett steeped a quantity of fibrin in nitric acid diluted with thrice its weight of water for 15 days. The acid acquired a yellow tinge, and possessed all the properties of the nitric solution of albumen. The fibrin thus treated, dissolved in boiling water, and when concentrated by evaporation, became a gelatinous mass, soluble in hot water, and precipitated by tan and nitromuriate of tin, and therefore possessing the properties of gelatine. Ammonia dissolves the greater part of the fibrin after it has been altered by nitric acid. The solution is of a deep orange colour, similar to the solution of albumen treated in the same way. Boiling nitric acid dissolves fibrin, except some fatty matter which swims on the surface. The solution resembles that of albumen; except that ammonia throws down a white precipitate, consisting chiefly of oxalate of lime. During the solution, prussic acid comes over, and carbonic acid gas mixed with nitrous gas; a considerable portion of oxalic acid is formed besides the fatty matter which swims.

The alkalies, while diluted, have but little effect upon fibrin; but when concentrated potash, or soda is boiled upon it, a complete solution is obtained of a deep brown colour possessing the properties of soap. During the solution ammonia is disengaged. When the solution is saturated with muriatic acid, a precipitate is obtained similar to that from animal soap, except that it sooner becomes hard and soapy when exposed to the air.

The earths, as far as is known, have little or no action on fibrin. Neither has the action of the metallic oxides and salts been examined.

Fibrin is insoluble in alcohol, ether, and oils. The effect of other re-agents on it has not been examined.

From the properties above detailed, fibrin appears to be composed of the same constituents as gelatine and albumen; but it contains more carbon and azote, and less oxygen. According to the experiments of Thenard and Gay-Lussac, its constituents are as follows:

Composition.

Carbon	53.360
Oxygen	19.681
Hydrogen	7.021
Azote	19.934
	100

The close resemblance which it bears to albumen, is very obvious from the experiments of Hatchett, just detailed. Nitric acid converts both into *gelatine*, and alkalies convert both into a species of *oil*. Now, as all the soft parts of animals consist of combinations of these three genera, it follows, as Mr Hatchett has observed, that all the soft parts of animals may be either converted into gelatine or animal soap, both substances of the highest importance.

Fibrin exists only in the blood and the muscles of animals; but it is a genus which includes as many species as there are varieties in the muscles of animals; and the great diversity of these substances is well known. The muscles of fish, of fowl, and of quadrupeds, bear scarcely any resemblance to each other.

Sect. V. *Of Urea.*

Urea.

Urea may be obtained by the following process: Evaporate by a gentle heat a quantity of human urine, voided six or eight hours after a meal, till it be reduced to the consistence of a thick syrup. In this state, when put by to cool, it concretes into a crystalline mass. Pour at different times upon this mass four times its weight of alcohol, and apply a gentle heat; a great part of the mass will be dissolved, and there will remain only a number of saline substances. Pour the alcohol solution into a retort, and distil by the heat of a sand bath, till the liquid, after boiling some time, is reduced to the consistence of a thick syrup. The whole of the alcohol is now separated, and what remains in the retort crystallizes as it cools. These crystals consist of the substance known by the name of *urea*.

How obtained.

Its properties.

Urea, obtained in this manner, has the form of crystalline plates crossing each other in different directions. Its colour is yellowish-white: it has a fetid smell, somewhat resembling that of garlic or arsenic; its taste is strong and acrid, resembling that of ammoniacal salts; it is very viscid and difficult to cut, and has a good deal of resemblance to honey. When exposed to the open air, it very soon attracts moisture, and is converted into a thick brown liquid. It is extremely soluble in water; and during its solution a considerable degree of cold is produced. Alcohol dissolves it with facility, but scarcely in so large a proportion as water. The alcohol solution yields crystals much more readily on evaporation than the solution in water.

When nitric acid is dropt into a concentrated solution of urea in water, a great number of bright pearl-coloured crystals are deposited, composed of urea and nitric acid. No other acid produces this singular effect. The concentrated solution of urea in water is brown, but it becomes yellow when diluted with a large quantity of water. The infusion of nutgalls gives it a yellowish-brown colour, but causes no precipitate; neither does the infusion of tan produce any precipitate.

When heat is applied to urea, it very soon melts, swells up, and evaporates with an insupportably fetid odour. When distilled, there comes over first benzoic acid, then carbonate of ammonia in crystals, some carbureted hydrogen gas, with traces of prussic acid and oil; and there remains behind a large residuum, composed of charcoal, muriate of ammonia, and muriate of soda. The distillation is accompanied with an almost insupportably fetid alliaceous odour.

When the solution of urea in water is kept in a boiling heat, and new water is added as it evaporates, the urea is gradually decomposed, a very great quantity of carbonate of ammonia is disengaged, and at the same time acetic acid is formed, and some charcoal precipitates.

When a solution of urea in water is left to itself for some time, it is gradually decomposed. A froth collects on its surface; air bubbles are emitted, which have a strong disagreeable smell, in which ammonia and acetic acid are distinguishable. The liquid contains a quantity of acetic acid. The decomposition is much more rapid if a little gelatine be added to the solution. In that case more ammonia is disengaged, and the proportion of acetic acid is not so great.

When the solution of urea is mixed with one-fourth of its weight of diluted sulphuric acid, no effervescence takes place; but, on the application of heat, a quantity of oil appears on the surface, which concretes upon cooling; the liquid which comes over into the receiver contains acetic acid, and a quantity of sulphate of ammonia remains in the retort dissolved in the undistilled mass. By repeated distillations, the whole of the urea is converted into acetic acid and ammonia.

When nitric acid is poured upon crystallized urea, a violent effervescence takes place, the mixture froths, assumes the form of a dark red liquid, great quantities of nitrous gas, azotic gas, and carbonic acid gas, are disengaged. When the effervescence is over, there remains only a concrete white matter, with some drops of reddish liquid. When heat is applied to this residuum, it detonates like nitrate of ammonia.

Muriatic acid dissolves urea, but does not alter it. Oxymuriatic acid gas is absorbed very rapidly by a diluted solution of urea; small whitish flakes appear, which soon become brown, and adhere to the sides of the vessel like a concrete oil. After a considerable quantity of oxymuriatic acid had been absorbed, the solution, left to itself, continued to effervesce exceeding slowly, and to emit carbonic acid and azotic gas. After this effervescence was over, the liquid contained muriate and carbonate of ammonia.

Urea is dissolved very rapidly by a solution of potash or soda, and at the same time a quantity of ammonia is disengaged; the same substance is disengaged when urea is treated with barytes, lime, or even magnesia. Hence it is evident, that this appearance must be ascribed to the muriate of ammonia, with which it is constantly mixed. When pure solid potash is triturated with urea, heat is produced, a great quantity of ammonia is disengaged; the mixture becomes brown, and a substance is deposited, having the appearance of an empyreumatic oil. One part of urea and two of potash, dissolved in four times its weight of water, when distilled, give out a great quantity of ammoniacal water; the residuum contains acetate and carbonate of potash.

When muriate of soda is dissolved in a solution of urea in water, it is obtained by evaporation, not in cubic crystals, its usual form, but in rectangular octahedrons. Muriate of ammonia, on the contrary, which crystallizes naturally in octahedrons, is converted into cubes, by dissolving and crystallizing it in the solution of urea.

Sect. VI. *Of Saccharine Matter.*

Saccharine matter in animal substances.

Sugar has never been found in animals in every respect similar to the sugar of vegetables; but there are certain animal substances which have so many properties in common with sugar, that they can scarcely be arranged under any other name. These substances are,

1. Sugar of milk.
2. Honey.
3. Sugar of diabetic urine.

Sugar of milk.

1. Sugar of milk may be obtained by the following process: Let fresh whey be evaporated to the consistence of honey, and then allowed to cool; it concretes into a solid mass. Dissolve this mass in water, clarify it with the white of eggs, filter and evaporate to the consistence of a syrup; it deposites, on cooling, a number of brilliant white cubic crystals, which are *sugar of milk*.

When pure, it has a white colour, a sweetish taste, and no smell. Its crystals are semitransparent regular parallelopipeds, terminated by four-sided pyramids. Its specific gravity, at the temperature of 55°, is 1.543. At that temperature it is soluble in seven times its weight of water; but is perfectly insoluble in alcohol. When burnt, it emits the odour of caromel, and exhibits precisely the appearance of burning sugar. When distilled, it yields the same products as sugar, only the empyreumatic oil obtained has the odour of benzoic acid. When treated with nitric acid, it yield *saclactic* acid. From these experiments, it appears that sugar of milk is specifically different from every kind of vegetable sugar at present known. Its constituents, according to the experiments of Thenard and Gay-Lussac, are as follows:

Oxygen	53.834
Carbon	38.825
Hydrogen	7.341
	100

Honey.

2. Honey is prepared by bees, and perhaps rather belongs to the vegetable than the animal kingdom. It has a white or yellowish colour, a soft and grained consistence, a saccharine and aromatic smell. By distillation it affords an acid phlegm and an oil, and its coal is light and spongy like that of the mucilages of plants. Nitric acid extracts from it oxalic acid, precisely as it does from sugar. It is very soluble in water, with which it forms a syrup, and like sugar passes to the vinous fermentation.

According to Proust, there are two kinds of honey; one always liquid, and the other solid and not deliquescent. They may be separated, he says, by means of alcohol.

Sugar of diabetic urine.

3. The urine of persons labouring under the disease known to physicians by the name of *diabetes*, yields, when evaporated, a considerable quantity of matter which possesses properties analogous to sugar. This seems to have been first observed by Willis. When treated with nitric acid, it yielded the same proportion of oxalic acid as an equal quantity of common sugar would have done, making allowance for the saline substances present. No saclactic acid was formed. Hence it follows, that this substance is not analogous to sugar of milk, but nearer common sugar in its properties. It has been supposed incapable of crystallizing regularly like common sugar. But we have seen it prepared by Dr Wollaston in small grains, having almost exactly the appearance of common white sugar.

SECT. VII. *Of Oils.*

Oils.

The oily substances found in animals belong all to the class of fixed oils. They differ very much in their consistence, being found in every intermediate state, from spermaceti, which is perfectly solid, to train oil, which is completely liquid. The most important of them are the following:

Spermaceti.

1. *Spermaceti.*—This peculiar oily substance is found in the cranium of the *physeter macrocephalus*, or spermaceti whale. It is obtained also from some other species. At first it is mixed with some liquid oil, which is separated by means of a woollen bag. The last portions are removed by an alkaline ley, and the spermaceti is afterwards purified by fusion. Thus obtained, it is a beautiful white substance, usually in small scales, very brittle, has scarcely any taste, and but little smell. It is distinguished from all other fatty bodies by the crystalline appearance which it always assumes. It melts, according to the experiments of Bostock, at the temperature of 112°. When sufficiently heated, it may be distilled over without much alteration; but when distilled repeatedly, it loses its solid form, and becomes a liquid oil.

Fat.

2. *Fat.*—This substance is found abundantly in different parts of animals. When pure, it possesses the properties of the fixed oils. Its consistence varies from *tallow* or *suet*, which is brittle, to *hog's lard*, which is soft and semi-fluid. To obtain fat pure, it is cut in small pieces, well washed in water, and the membranous parts and vessels separated. It is then melted in a shallow vessel along with some water, and kept melted till the water is completely evaporated. Thus purified, it is white, tasteless, and nearly insipid.

Train oil.

3. *Train oil.*—This liquid is extracted from the blubber of the whale, and from other fish. It forms a very important article of commerce, being employed for combustion in lamps, and for other purposes. It is at first thick; but, on standing, a white mucilaginous matter is deposited, and the oil becomes transparent. It is then of a reddish brown colour, and has a disagreeable smell.

Animal oil of Dippel.

4. Though all the oily bodies found in animal substances belong to the class of fixed oils, yet there is a peculiar volatile oil which makes its appearance, and which is doubtless formed during the distillation of different animal bodies. Though this oil has now lost that celebrity which drew the attention of the older chemists to it, yet, as its properties are peculiar, a short account of it will not be improper. It it usually called the *animal oil of Dippel*, because that chemist first drew the attention of chemists to it. It is usually obtained from the gelatinous and albuminous parts of animals. The horns are said to answer best. The product of the first distillation is to be mixed with water, and distilled with a moderate heat; the oil which is first obtained is the animal oil of Dippel.

It is colourless and transparent; its smell is strong and rather aromatic; it is almost as light and as volatile as ether; water dissolves a portion of it; and it changes syrup of violets green, owing, as is supposed, to its containing a little ammonia. The acids all dissolve it, and form with it a kind of imperfect soap. Nitrous acid sets it on fire. It forms with alkalies a soap. Alcohol, ether, and oils, unite with it. When exposed to the air it becomes brown, and loses its transparency. It was formerly used as a specific in fevers.

SECT. VIII. *Of Animal Resins.*

Animal resins, viz.

Substances resembling resins are found in different animal bodies, and which, for that reason, may be called *animal resins*. Their properties are somewhat different from the vegetable resins, but they have not been all examined with precision. The following are the most remarkable of these substances.

Resin of bile.

1. *Resin of bile.* This substance may be obtained by the following process: Into thirty-two parts of fresh ox bile pour one part of concentrated muriatic acid. After the mixture has stood for some hours, pass it through a filter, in order to separate a white coagulated substance. Pour the filtrated liquor, which has a fine green colour, into a glass vessel, and evaporate it by a moderate heat. When it has arrived at a certain degree of concentration, a green-coloured substance precipitates. Decant off the clear liquid, and wash the precipitate in a small quantity of pure water. This precipitate is the *basis of bile*, or the *resin of bile*, as it is sometimes called.

The resin of bile is of a dark brown colour; but when spread out upon paper or on wood it is a fine grass green. Its taste is intensely bitter.

When heated to about 122° it melts; and if the heat be still farther increased, it takes fire and burns with rapidity. It is insoluble in water, but soluble in alcohol; and water precipitates it from that liquid.

It is soluble also in alkalies, and forms with them a compound, which has been compared to a soap. Acids, when sufficiently diluted, precipitate it both from water and alkalies without any change; but if they be concentrated, the precipitate is re-dissolved.

Ambergris.

2. *Ambergris.* This substance is found floating on the sea, near the coasts of India, Africa, and Brazil, usually in small pieces, but sometimes in masses of fifty or one hundred pounds weight. Various opinions have been entertained concerning its origin. Some affirmed that it was the concrete juice of a tree; others thought it a bitumen; but it is now considered as pretty well established, that it is a concretion formed in the stomach or intestines of the *physeter macrocephalus*, or spermaceti whale. See AMBERGRIS.

Ambergris when pure, is a light soft substance which swims on water. Its specific gravity varies from 0.78 to 0.92, according to Brissen. Bouillon La Grange, who has lately published an analysis of it, found its specific gravity from 0.849 to 0.844. Its colour is ash grey, with brownish-yellow and white streaks. It has an agreeable smell, which improves by keeping. Its taste is insipid.

According to Bouillon La Grange, it is composed of

52.7	adipocire.
30.8	resin.
11.1	benzoic acid.
5.4	charcoal.
100.0	

Castor.

3. *Castor.* This substance is obtained from the beaver. In each of the inguinal regions of that animal there are two bags, a large and a small. The large one contains the true castor; the small one a substance which has some resemblance to it, but which is in much less estimation. We are indebted to Bouillon La Grange for a set of experiments on it.

Castor is of a yellow colour, and when newly taken from the animal it is nearly fluid. But by exposure to the atmosphere it gradually hardens, becomes darker coloured, and assumes a resinous appearance. Its taste is bitter and acrid, and its odour strong and aromatic.

From the analysis of Bouillon La Grange, we learn that castor contains the following ingredients:

1. Carbonate of potash.
2. Carbonate of lime.
3. Carbonate of ammonia.
4. Iron.
5. Resin.
6. A mucilaginous extractive matter.
7. A volatile oil.

The properties of the resin are analogous to those of the resin of bile.

SECT. IX. *Of Acids.*

Acids found in animals, viz.

The acids which have been discovered ready formed, and constituting a part of animal bodies, are the following:

1. Phosphoric.
2. Sulphuric.
3. Muriatic.
4. Carbonic.
5. Benzoic.
6. Uric.
7. Rosacic.
8. Amniotic.
9. Oxalic.
10. Formic.
11. Acetic.
12. Malic.

Phosphoric,

1. The phosphoric acid is by far the most abundant of all the acids found in animals. Combined with lime, it constitutes the basis of bone; and the phosphate of lime is found in the muscles, and almost all the solid parts of animals; neither are there many of the fluids from which it is absent. In the blood, phosphoric acid is found combined with oxide of iron; and in the urine it exists in excess, holding phosphate of lime in solution.

Sulphuric,

2. Sulphuric acid can scarcely be considered as a component part of any of the substances belonging to the human body. It is said, indeed, to occur sometimes in urine combined with soda. It is, however, a very common constituent of the liquid contents of the inferior animals. Thus sulphate of soda is found in the liquor of the amnios of cows, and sulphate of lime occurs usually in the urine of quadrupeds.

Muriatic,

3. Muriatic acid occurs in most of the fluid animal substances, and is almost always combined with soda, constituting common salt.

Carbonic,

4. Carbonic acid has been detected in fresh human urine by Proust, and it occurs in the urine of horses and cows abundantly, partly combined with lime.

Benzoic,

5. Benzoic acid was first discovered in human urine by Scheele; and Fourcroy and Vauquelin have found it abundantly in the urine of cows. Proust has detected it in the blood, the albumen of an egg, in glue, silk, and wool, in the sponge, different species of algæ, and even in mushrooms.

Uric,

6. Uric or lithic acid was discovered by Scheele in 1776. It is the most common constituent of urinary calculi, and exists also in human urine. That species of calculus which resembles wood in its colour and appearance, is composed entirely of this substance. It was called at first lithic acid; but this name, in consequence of the remarks made by Dr Pearson on its impropriety, has been laid aside, and that of *uric* acid substituted in its place.

Rosacic,

7. Rosacic. During intermittent fevers, urine deposites a very copious precipitate, which has been long known to physicians under the name of *lateritious sediment.* This sediment always makes its appearance at the crisis of fevers. In gouty people, the same sediment appears in equal abundance towards the end of a paroxysm of the disease; and if this sediment suddenly disappears after it has begun to be deposited, a fresh attack may be expected. Scheele considered this sediment as uric acid mixed with some phosphate of lime; and the same opinion has been entertained by other chemists; but Proust affirms, that it consists chiefly of a different substance, to which he has given the name of *rosacic* acid from its colour, mixed with a certain proportion of uric acid and phosphate of lime. This rosacic acid, he informs us, is distinguished from the uric by the facility with which it dissolves in hot water, the violet precipitate which it occasions in muriate of gold, and by the little tendency which it has to crystallize. The experiments of Proust have lately been confirmed by those of Vauquelin.

Amniotic,

8. Amniotic acid has been lately discovered by Vauquelin and Buniva in the liquor of the amnios of the cow, and may be obtained in white crystals, by evaporating that liquid slowly. Hence they have given it the name of *amniotic acid.* It is of a white and brilliant colour; its taste has a very slight degree of sourness; it reddens the tincture of turnsole; it is scarcely soluble in cold water, but very readily in hot water, from which it separates in long needles as the solution cools. It is soluble also in alcohol, especially when assisted by heat.

Oxalic,

9. Oxalic acid has hitherto been found only in a few urinary calculi by Vauquelin and Fourcroy.

Formic. 10. Formic acid has been hitherto found only in the *formica rufa*, or red ant.

Acetic. 11. Acetic. This acid has been detected in urine by Proust. It exists also in the *formica rufa*, or red ant, as has been demonstrated by the experiments of Fourcroy and Vauquelin. It appears also, from the labours of these philosophers and of Thenard, that the acid found in milk is the acetic, disguised a little by holding some salts in solution.

Malic. 12. Malic acid. This acid has been lately detected by Fourcroy and Vauquelin, in the acid liquid obtained from the *formica rufa*. When this liquid is saturated with lime, if acetate of lead be dropt into the solution, a copious precipitate falls, which is soluble in acetic acid. Fourcroy and Vauquelin exposed the precipitate to the proper trials, and ascertained that it was malate of lead.

SECT. X. *Of Alkalies, Earths, and Metals.*

Alkalies found in animals. I. All the alkalies have been found in the fluids of animals.

Potash, 1. Potash is rather uncommon in the human fluids; but it has been detected in the milk of cows, and it has been found abundantly in the urine of quadrupeds.

Soda, 2. Soda exists in all the fluids, and seems always to be combined with albumen. Phosphate and muriate of soda are also found. It is this alkali which gives animal fluids the property of tinging vegetable blues green.

Ammonia. 3. Ammonia has been detected by Proust in urine; and it is formed in abundance during the putrefaction of most animal bodies.

Earths found in animals. II. The only earths hitherto found in animals are lime, magnesia, and silica.

Lime, 1. Lime exists in great abundance in all the larger animals. Combined with phosphoric acid, it constitutes the basis of bones, while shells are composed of carbonate of lime. Phosphate of lime is found also in the muscles and other solid parts, and it is held in solution by almost all the fluids.

Magnesia, 2. Magnesia has been detected in human urine by Fourcroy and Vauquelin, combined with phosphoric acid and ammonia. It constitutes also sometimes a component part of the urinary calculi.

Silica. 3. Silica has not hitherto been detected in any of the component parts of animals, except hair; but Fourcroy and Vauquelin found it in urinary calculi.

Metals found in animals. III. The metals found in animals are two; namely, iron and manganese.

Iron, 1. Iron combined with phosphoric acid is a constituent part of the blood. Its presence was first ascertained by Menghini, who proved at the same time that it does not exist in the solid parts of animals. It is said to exist also in bile.

Manganese. 2. Manganese has been found in human hair, but scarcely in any other animal substance.

CHAP. II.

Parts of Animals.

Parts of animals. THE different substances which compose the bodies of animals may be arranged under the following heads:

1. Bones and shells.
2. Horns and nails.
3. Muscles.
4. Skin.
5. Membranes.
6. Tendons and ligaments.
7. Glands.
8. Brain and nerves.
9. Marrow.
10. Hair and feathers.
11. Silk and similar bodies.

Besides these substances, which constitute the solid parts of the bodies of animals, there are a number of fluids, the most important of which is the *blood*, which pervades every part of the system in all the larger animals. The rest are known by the name of *secretions*, because they are formed, or *secreted* as the anatomists term it, from the blood. The principal animal secretions are the following:

1. Milk.
2. Eggs.
3. Saliva.
4. Pancreatic juice.
5. Bile.
6. Cerumen.
7. Tears.
8. Liquor of the pericardium.
9. Humours of the eye.
10. Mucus of the nose, &c.
11. Sinovia.
12. Semen.
13. Liquor of the amnios.
14. Poisonous secretions.
15. Air.

Various substances are separated either from the blood or the food, on purpose to be afterwards thrown out of the body as useless or hurtful. These are called *excretions*. The most important of them are,

1. Sweat.
2. Urine.
3. Fæces.

Besides the liquids which are secreted for the different purposes of healthy animals, there are others which make their appearance only during disease, and which may therefore be called *morbid secretions*. The most important of these are the following:

1. Pus.
2. The liquor of dropsy.
3. The liquor of blisters.

To these we must add several solid bodies, which are occasionally formed in different cavities, in consequence of the diseased action of the parts. They may be called *morbid concretions*. The most remarkable of them are the following:

1. Salivary calculi.
2. Concretions in the lungs, liver, brain, &c.
3. Intestinal calculi.
4. Biliary calculi.
5. Urinary calculi.
6. Gouty calculi.

These different substances shall form the subjects of the following Sections:

SECT. I. *Of Bones, Shells, and Crusts.*

Bones. By *bones* are meant those hard, solid, well-known substances, to which the firmness, shape, and strength of animal bodies are owing; which, in the larger animals, form, as it were, the ground-work upon which all the rest is built. In man, in quadrupeds, and many other animals, the bones are situated below the other parts, and scarcely any of them are exposed to view; but shell-fish and snails have a hard covering on the outside of their bodies, evidently intended for defence. As these coverings, though known by the name of *shells*, are undoubtedly of a bony matter, we shall include them in this Section.

1. *Bones.*

Their properties. The bones are the most solid parts of animals. Their texture is sometimes dense, at other times cellular and porous, according to the situation of the bone. They are white, of a lamellar structure, and not flexible nor softened by heat. Their specific gravity differs in different parts. That of adults' teeth is 2.2727; the specific gravity of children's teeth is 2.0833.

The component parts of bones are chiefly four; namely, the earthy salts, fat, gelatine, and cartilage.

1. The earthy salts may be obtained either by calcining the bone to whiteness, or by steeping it for a sufficient length of time in acids. In the first case, the salts remain in the state of a brittle white substance; in the second they are dissolved, and may be thrown down by the proper precipitants. These earthy salts are four in number: 1. Phosphate of lime, which constitutes by far the greatest part of the whole. 2. Carbonate of lime. 3. Phosphate of magnesia, lately discovered by Fourcroy and Vauquelin. It occurs in the bones of all the inferior animals examined by these indefatigable chemists, but could not be detected in human bones. 4. Sulphate of lime, detected by Mr Hatchett in a very minute proportion.

2. The proportion of fat contained in bones is various. By breaking bones in small pieces, and boiling them for some time in water, Mr Proust obtained their fat swimming on the surface of the liquid. It weighed, he says, one-fourth of the weight of the bones employed. This proportion appears excessive, and can scarcely be accounted for, without supposing that the fat still retained water.

3. The gelatine is separated by the same means as the fat, by breaking the bones in pieces and boiling them long enough in water. The water dissolves the gelatine, and gelatinizes when sufficiently concentrated. Hence the importance of bones in making portable soups, the basis of which is concrete gelatine, and likewise in making glue. By this process, Proust obtained from powdered bones about one-sixteenth of their weight of gelatine.

4. When bones are deprived of their gelatine by boiling them in water, and of their earthy salts by steeping them in diluted acids, there remains a soft white elastic substance, possessing the figure of the bones, and known by the name of *cartilage*. From the experiments of Hatchett, it appears that this substance has the properties of coagulated albumen. Like that substance, it becomes brittle and semitransparent when dried, is readily soluble in hot nitric acid, is converted into gelatine by the action of diluted nitric acid; for it is soluble in hot water, and gelatinises on cooling, and ammonia dissolves it and assumes a deep orange colour.

Composition.

Ox bones, according to the analysis of Fourcroy and Vauquelin, are composed of

51.0	solid gelatine.
37.7	phosphate of lime.
10.0	carbonate of lime.
1.3	phosphate of magnesia.
100.0	

From the calcined bones of horses and sheep, fowls, and fishes, they extracted about one-thirtysixth part of phosphate of magnesia. More lately, these eminent chemists detected the same constituents in human bones.

The only bone hitherto observed altogether destitute of cartilage is the enamel of the teeth. When the raspings of bones are steeped in diluted acids, the cartilage alone remains undissolved. Now, when the raspings of enamel are treated in this manner, Mr Hatchett observed, that the whole was dissolved without any residuum whatever. If we believe Fourcroy and Vauquelin, the enamel of teeth is composed of

72.9	phosphate of lime.
27.1	gelatine and water.
100.0	

But the most complete analysis of teeth has been made by Mr Pepys, and his results agree exactly with those of Hatchett. He found the enamel of the teeth composed of

78	phosphate of lime.
6	carbonate of lime.
16	loss and water.
100	

2. *Shells.*

Shells.

Under the name of *shells* we include all the bony coverings of the different species of shell fish. Egg shells, also, from the similarity of their texture, belong to the same head. For almost all the knowledge of these substances that we possess, we are indebted to the late important dissertations of Mr Hatchett. A few detached facts, indeed, had been observed by other chemists; but his experiments gave us a systematic view of the constituents of the whole class.

Shells, like bones, consist of calcareous salts united to a soft animal matter; but in them the lime is united chiefly to carbonic acid, whereas in bones it is united to phosphoric acid. In shells, the predominating ingredient is carbonate of lime; whereas in bones, it is phosphate of lime. This constitutes the characteristic difference in their composition.

Mr Hatchett has divided shells into two classes. The first are usually of a compact texture, resemble porcelain, and have an enamelled surface, often finely variegated. The shells belonging to this class have been distinguished by the name of *porcelaneous shells*. To this class belong the various species of *voluta*, *cypræa*, &c. The shells belonging to the second class are usually covered with a strong epidermis, below which lies the shell in layers, and composed entirely of the substance well known by the name of *mother-of-pearl*. They have been distinguished by the name of *mother-of-pearl shells*. The *shell* of the *fresh water muscle*, the *haliotis iris*, the *turbo olearius*, are examples of such shells. The shells of the first of these classes contain a very small portion of soft animal matter; those of the second contain a very large portion. Hence we see that they are extremely different in their composition.

Porcelaneous shells.

1. Porcelaneous shells, when exposed to a red heat, crackle and lose the colour of their enamelled surface. They emit no smoke or smell; their figure continues unaltered, their colour becomes opake white, tinged partially with pale grey. They dissolve when fresh with effervescence in acids, and without leaving any residue; but if they have been burnt, there remains always a little charcoal. The solution is transparent, gives no precipitate with ammonia or acetate of lead; of course it contains no sensible portion of phosphate or sulphate of lime. Carbonate of ammonia throws down an abundant precipitate of carbonate of lime. Porcelaneous shells, then, consist of carbonate of lime cemented together by a small portion of an animal matter, which is soluble in acids, and therefore resembles gelatine.

Mother-of-pearl shells.

2. Mother-of-pearl shells, when exposed to a red heat, crackle, blacken, and emit a strong fetid odour. They exfoliate, and become partly dark grey, partly a fine white. When immersed in acids they effervesce at first strongly; but gradually more and more feebly, till at last the emission of air-bubbles is scarcely perceptible. The acids take up only lime, and leave a number of thin membranous substances, which still retain the form of the shell. From Mr Hatchett's experiments we learn, that these membranes have the properties of coagulated

albumen. Mother-of-pearl shells, then, are composed of alternate layers of coagulated albumen, and carbonate of lime, beginning with the epidermis, and ending with the last formed membrane.

Pearl.

Pearl, a well known globular concretion which is formed in some of these shells, resembles them exactly in its structure and composition. It is a beautiful substance, of a bluish white colour, iridescent, and brilliant. It is composed of concentric and alternate coats of thin membrane and carbonate of lime. Their iridescence is obviously the consequence of the lamellated structure.

3. *Crusts.*

Crusts.

By crusts we understand those bony coverings of which the whole external surface of crabs, lobsters, and other similar sea animals are composed. Mr Hatchett found them composed of three ingredients: 1. A cartilaginous substance, possessing the properties of coagulated albumen; 2. Carbonate of lime; 3. Phosphate of lime. By the presence of this last substance they are essentially distinguished from shells; and by the great excess of carbonate of lime above the phosphate, they are equally distinguished from bones. Thus the crusts lie intermediate between bones and shells, partaking of the properties and constitution of each. The shells of the eggs of fowls must be referred likewise to the class of crusts, since they contain both phosphate and carbonate of lime. The animal cement in them, however, is much smaller in quantity. From the experiments of Berniard and Hatchett, it is extremely probable that the shells of snails are composed likewise of the same ingredients, phosphate of lime having been detected in them by these chemists.

SECT. II. *Of Horns, Nails, and Scales.*

In the last Section we treated of those hard parts of animals which were inflexible and incapable of being softened by heat, and which contained a great portion of calcareous salts; but there is another set of hard parts which possess considerable elasticity, which are softened by heat, and which contain but a very small portion of calcareous matter. This set comprehends the substances well known under the names of *horn*, *nails*, and *scales*.

Horns.

1. *Horns* are well known substances that are attached to the foreheads of oxen, sheep, and various other animals. They are not very hard, as they may be easily cut with a knife or rasped with a file; but they are so tough, as not to be capable of being pounded in a mortar. When in thin plates, they have a degree of transparency, and have been sometimes substituted for glass in windows. When heated sufficiently they become very soft and flexible, so that their shape may be altered considerably. Hence they may be gradually squeezed into a mould, and wrought into various forms, as is well known. When strongly heated in a Papin's digester, they are said to be converted into a gelatinous mass, which possesses the properties of gelatine.

The quantity of earthy matter which they contain is exceedingly small. Mr Hatchett burnt 500 grains of ox horn. The residuum was only 1.5 grain, and not the half of this was phosphate of lime. Seventy-eight grains of the horn of the chamois left only 0.5 of residue, of which less than the half was phosphate of lime. They consist chiefly of a membranous substance, which possess the properties of coagulated albumen; and probably they contain also a little gelatine.

Nails.

2. The *nails*, which cover the extremities of the fingers, are attached to the epidermis, and come off along with it. Mr Hatchett has ascertained that they are composed chiefly of a membranous substance, which possesses the properties of coagulated albumen. They seem to contain also a little phosphate of lime. Water softens, but does not dissolve them; but they are readily dissolved and decomposed by concentrated acids and alkalies. Hence it appears that nails agree with horn in their nature and composition. Under the head of nails must be comprehended the talons and claws of the inferior animals, and likewise their hoofs, which differ in no respect from horn.

Scales.

3. *Scales* of animals are of two kinds; some, as those of serpents and other amphibious animals, have a striking resemblance to horn; while those of fish bear a greater resemblance to mother-of-pearl. The composition of these two kinds of shells is very different.

The scales of fish are composed of different membranous laminæ. When immersed for four or five hours in nitric acid, they become transparent, and perfectly membranaceous. The acid, when saturated with ammonia, gives a copious precipitate of phosphate of lime. Hence they are composed of alternate layers of membrane and phosphate of lime. To this structure they owe their brilliancy. Mr Hatchett found the spicula of the shark's skin to be similar in its composition, but the skin itself yielded no phosphate of lime.

The horny scales of serpents, on the other hand, are composed alone of a horny membrane, and are destitute of phosphate of lime. They yielded, when boiled, but slight traces of gelatine; the horn-like crusts which cover certain insects and other animals, appear, from Mr Hatchett's experiments, to be nearly similar in their composition and nature.

SECT. III. *Of the Muscles of Animals.*

Muscles of animals.

After the hard parts of animals have been examined, it remains for us to consider the composition of the *soft* parts. Of these, the muscles naturally claim our attention in the first place, as being the most important.

The muscular parts of animals are known, in common language, by the name of *flesh*. They constitute a considerable portion of the food of man.

Muscular flesh is composed of a great number of fibres or threads, commonly of a reddish or whitish colour; but its appearance is too well known to require any description. Hitherto it has not been subjected to any accurate chemical analysis.

When a muscle is cut in small pieces, and well washed with water, the blood and other liquids contained in it are separated, and part of the muscular substance also is dissolved. The muscle, by this process, is converted into a white fibrous substance, still retaining the form of the original body. The water assumes the colour which results from mixing water with some blood. When heated it coagulates; brown flakes swim on the surface, consisting of albumen combined with the colouring matter of the blood: some fibrin likewise precipitates. If the evaporation be continued, more albumen precipitates, and at last the whole assumes the form of a jelly. When evaporated to dryness, and treated with alcohol, the gelatine thus formed, together with a little phosphate of soda and of ammonia, remains undissolved; but the alcohol dissolves a peculiar *extractive* matter, first observed by Thouvenel. This matter may be obtained by evaporating the alcohol to dryness. It has a reddish brown colour, a strong acrid taste, and aromatic odour.

If the muscle, after being thus treated with cold water, be boiled for a sufficient time in water, an additional portion of the same substances is separated from it. Some albumen collects on the surface in the form of scum, accompanied with some melted fat. The water, when sufficiently concentrated by evaporation, assumes the form of a jelly. When evaporated to dryness, and treated with alcohol, the gelatine and phosphoric salts remain, while the extractive matter of Thouvenel is dissolved, and may be obtained by evaporating to dryness.

The muscle, thus treated with water, is left in the state of grey fibres, insoluble in water, and becoming brittle when dry. This substance possesses all the properties of *fibrin*.

From these facts, ascertained by Thouvenel and Fourcroy, it appears that the muscles are composed chiefly of fibrin, to which they owe their fibrous structure and their form, and that they contain also,

1. Albumen.
2. Gelatine.
3. Extractive.
4. Phosphate of soda.
5. Phosphate of ammonia.
6. Phosph. of lime and carb. of do.

For the discovery of the last ingredients we are indebted to Mr Hatchett, who found that 500 parts of beef muscle left, after combustion, a residuum of 25.6 parts, consisting chiefly of these salts.

The muscles of different animals differ exceedingly from each other in their appearance and properties, at least as articles of food; but we know little of their chemical differences. The observations of Thouvenel alone were directed to that object, and they are imperfect. The flesh of the *ox* contains, according to him, the greatest quantity of insoluble matter, and leaves the greatest residuum when dried; the flesh of the *calf* is more aqueous and mucous: the land and water *turtle* yields more matter to water than the muscle of the ox; but Thouvenel ascribes the difference to foreign bodies, as ligaments, &c. mixed with the muscle of the turtle: *snails* yield to water a quantity of matter intermediate between that given by beef and veal; with them the muscles of *frogs, cray fish*, and *vipers*, agree nearly in this respect; but the muscles of fresh water fish, notwithstanding their softness, yield a considerably smaller proportion.

SECT. IV. *Of the Skin.*

Skin. The skin is that strong thick covering which envelopes the whole external surface of animals. It is composed chiefly of two parts: a thin white elastic layer on the outside, which is called *epidermis* or *cuticle;* and a much thicker layer, composed of a great many fibres closely interwoven, and disposed in different directions; this is called the *cutis*, or *true skin*. The *epidermis* is that part of the skin which is raised in blisters.

Epidermis. 1. The epidermis is easily separated from the cutis by maceration in hot water. It possesses a very great degree of elasticity.

It is totally insoluble in water and in alcohol. Pure fixed alkalies dissolve it completely, as does lime likewise, though slowly. Sulphuric and muriatic acids do not dissolve, at least they leave no sensible action on it for a considerable time; but nitric acid soon deprives it of its elasticity, and causes it to fall to pieces.

If the cuticle be tinged with nitric acid, the application of ammonia to it is well known to give it instantaneously a deep orange colour. Now, as Hatchett has shown that this change is also produced upon coagulated albumen in the same circumstances, and as the epidermis resembles that substance in all the properties above detailed, it can scarcely be doubted that it is any thing else than a peculiar modification of coagulated albumen.

Cutis. 2. The cutis is a thick dense membrane, composed of fibres interwoven like the texture of a hat. When it is macerated for some hours in water, and agitation and pressure are employed to accelerate the effect, the blood, and all the extraneous matter with which it was loaded, are separated from it, but its texture remains unaltered. On evaporating the water employed, a small quantity of gelatine may be obtained. No subsequent maceration in cold water has any farther effect. When distilled, it yields the same products as fibrin. The concentrated alkalies dissolve it, converting it into oil and ammonia. Weak acids soften it, render it transparent, and at last dissolve it. Nitric acid converts it into oxalic acid and fat, while, at the same time, azotic gas and prussic acid are emitted. When heated it contracts, and then swells, exhales a fetid odour, and leaves a dense charcoal, difficult to incinerate. By spontaneous decomposition in water or moist earth, it is converted into a fatty matter and into ammonia, which compose a kind of soap. When allowed to remain long in water, it softens and putrefies, being converted into a kind of jelly. When long boiled in water it becomes gelatinous, and dissolves completely, constituting a viscid liquor, which, by proper evaporation, is converted into glue. Hence the cutis of animals is commonly employed in the manufacture of glue.

From these facts, the cutis appears to be a peculiar modification of gelatine, enabled to resist the action of water, partly by the compactness of its texture, and partly by the viscidity of the gelatine of which it is formed; for those skins which dissolve most readily in boiling water afford the worst glue. Mr Hatchett has observed that the viscidity of the gelatine obtained from skins is nearly inversely as their flexibility, the supplest hides always yielding the weakest glue; but this glue is very soon obtained from them by hot water. The skin of the eel is very flexible, and affords very readily a great proportion of gelatine. The skin of the shark also readily yields abundance of gelatine; and the same remark applies to the skins of the hare, rabbit, calf, and ox; the difficulty of obtaining the glue and its goodness always increasing with the toughness of the hide. The hide of the rhinoceros, which is exceedingly strong and tough, far surpasses the rest in the difficulty of solution, and in the goodness of its glue. When skins are boiled, they gradually swell and assume the appearance of horn: then they dissolve slowly.

Rete mucosum. 3. As to the *rete mucosum*, or the mucous substance, situated between the cutis vera and epidermis, its composition cannot be determined with precision, because its quantity is too small to admit of examination. It is known that the black colour of negroes depends upon a black pigment, situated in this substance. Oxymuriatic acid deprives it of its black colour, and renders it yellow. A negro, by keeping his feet for some time in water impregnated with that acid, deprived it of its colour, and rendered it nearly white; but in a few days the black colour returned again with its former intensity. This experiment was first made by Dr Beddoes on the fingers of a negro.

SECT. V. *Of Membranes, Tendons, Ligaments, and Glands.*

These substances have not hitherto been subjected to a rigid chemical analysis. But from the properties which have been observed, they appear to have a closer resemblance to the skin than to any other animal substance.

Membranes.

1. The membranes are thin semitransparent bodies, which envelope certain parts of the body, especially the viscera; such as, the dura and pia mater, the plura, the peritoneum, the periosteum, &c. These substances are soft and pliable; when macerated in water, they swell, and become somewhat pulpy; and by continued decoction in hot water they are almost completely dissolved, and the solution concretes into gelatine. They are convertible, of course, into the same substance as the cutis by decoction; hence we must consider their composition as similar. Like hides, they may also be tanned and converted into leather. From the experiments of Mr Hatchett, it appears that they contain no phosphate of lime as a constituent part, and scarcely any saline ingredients; for when calcined, they leave but a very inconsiderable residuum. Thus 250 grains of hog's bladder left only 0.02 grain of residuum.

Tendons.

2. The tendons are strong, pearl-coloured, brilliant bodies, which terminate the muscles, and attach them to the bones, and are known in common language by the name of *sinews*. When boiled, they assume the form of a semitransparent gelatinous substance, of a pleasant taste, well known in boiled meat. If the decoction be continued, they dissolve completely, and are converted into gelatine. From these facts we are authorised to conclude, that the composition of the tendons is similar to that of the membranes and cutis.

Ligaments.

3. The ligaments are strong bands which bind the bones together at the different joints: they are fibrous substances, very dense and strong, and somewhat elastic. When boiled, they yield a portion of gelatine, but they resist the action of water with great obstinacy, and after a great deal of boiling retain their form, and even their strength. The ligaments, then, differ essentially from the two last species. How far they resemble coagulated albumen, remains to be ascertained. It is not unlikely that they will form a genus apart.

Glands.

4. The glands are a set of bodies employed to form or to alter the different liquids which are employed for different purposes in the animal body. There are two sets of them: the *conglobate*, which are small, scattered in the course of the lymphatics; and the *conglomerate*, such as the liver, kidneys, &c. Fourcroy supposes the first of these to be composed of gelatine; but this is not very probable. The structure of the large glands has been examined by anatomists with great care; but we are still ignorant of their composition. Indeed, the present state of chemistry scarcely admits of an accurate analysis of these complicated bodies.

SECT. VI. *Of the Brain and Nerves.*

Brain and nerves.

The brain and nerves are the instruments of sensation, and even of motion; for an animal loses the power of moving a part the instant that the nerves which enter it are cut.

The brain and nerves have a strong resemblance to each other; and it is probable that they agree also in their composition. But hitherto no attempt has been made to analyze the nerves. The only chemists who have examined the nature of *brain* are Mr Thouret and Mr Fourcroy.

The brain consists of two substances, which differ from each other somewhat in colour, but which, in other respects, seem to be of the same nature. The outermost matter, having some small resemblance in colour to wood-ashes, has been called the *cineritious* part; the innermost has been called the *medullary* part.

Properties of brain.

Brain has a soft feel, not unlike that of soap; its texture appears to be very close; its specific gravity is greater than that of water.

When brain is triturated in a mortar with diluted sulphuric acid, part is dissolved; the rest may be separated by filtration in the form of a coagulum. The acid liquor is colourless. By evaporation, the liquid becomes black, sulphurous acid is exhaled, and crystals appear; and when evaporated to dryness, a black mass remains behind. When this mass is diluted with water, a quantity of charcoal separates, and the water remains clear: The brain is completely decomposed, a quantity of ammonia combines with the acid, and forms sulphate of ammonia, while charcoal is precipitated. The water, by evaporation and treatment with alcohol, yields sulphates of ammonia and lime, phosphoric acid, and phosphates of soda and ammonia. Brain, therefore, contains

Phosphate of lime,
Phosphate of soda,
Phosphate of ammonia.

Traces also of sulphate of lime can be discovered in it. The quantity of these salts is very small; altogether they do not amount to $\frac{1}{100}$th part.

Diluted nitric acid, when triturated with brain, likewise dissolves a part, and coagulates the rest. The solution is transparent. When evaporated till the acid becomes concentrated, carbonic acid gas and nitrous gas are disengaged; an effervescence takes places, white fumes appear, an immense quantity of ammonia is disengaged, a bulky charcoal remains, mixed with a considerable quantity of oxalic acid.

When brain is gradually evaporated to dryness by the heat of a water bath, a portion of transparent liquid separates at first from the rest, and the residuum, when nearly dry, acquires a brown colour; its weight amounts to about one-fourth of the fresh brain. It may still be formed into an emulsion with water, but very soon separates again spontaneously.

When alcohol is repeatedly boiled upon this dried residuum, till it ceases to have any more action, it dissolves about five-eighths of the whole. When this alcohol cools, it deposites a yellowish white substance, composed of brilliant plates. When kneaded together by the fingers, it assumes the appearance of a ductile paste: at the temperature of boiling water it becomes soft, and when the heat is increased it blackens, exhales empyreumatic and ammoniacal fumes, and leaves behind it a charry matter. When the alcohol is evaporated, it deposites a yellowish black matter, which reddens paper tinged with turnsole, and readily diffuses itself through water.

Pure concentrated potash dissolves brain, disengaging a great quantity of ammonia.

SECT. VII. *Marrow.*

Marrow.

The hollows of the long bones are in living animals filled with a peculiar species of fat matter, to which the name of *marrow* has been given. In some bones this matter is a good deal mixed with blood, and has a red colour; in others, as the thigh bones, it is purer, and has a yellow colour. Various experiments on this matter were made by the older chemists, showing it to be analogous to animal fats, and pointing out some of its peculiarities. Berzelius has lately examined it in detail, and published the results of his experiments. The marrow on which his trials were made was obtained from the thigh bone of an ox.

Its properties.

Marrow, freed from its impurities, has a white colour with a shade of blue; its taste is insipid and rather sweetish. It softens by the heat of the hand, and melts when heated to 113°. When cooled slowly, it crystallizes in sphericles like olive oil. It burns with a flame like tallow. When distilled it gives first a transparent fluid yellowish oil, accompanied by carbonic acid gas, water, and heavy inflammable air. Afterwards there comes over a white solid oil, accompanied by a less copious evolution of gaseous bodies, and which does not become dark coloured, as happens when tallow is distilled. This had already been observed by Neumann. This solid oil has a disagreeable smell, amounts to 0.8 of the marrow distilled, reddens vegetable blues, and when boiled in water gives out a portion of sebacic acid, which Berzelius considers as benzoic acid.

The empyreumatic oil combines readily with alkalies and their carbonates. With the latter it forms a snow white soap, insoluble in water, though it increases in bulk when placed in contact with that liquid. It combines also with the earths, and forms soaps likewise insoluble in water.

The water which comes over during the distillation of marrow is colourless, has a fetid and sour smell, and an empyreumatic taste. It contains a little acetic acid, empyreumatic oil, and probably benzoic acid; but exhibits no traces of ammonia.

The gaseous products amount to one-tenth of the marrow distilled. They contain no sulphur nor phosphorus, and consist of carbonic acid and heavy inflammable air, which burns with a white flame, and seems to contain oil in solution.

The charry matter in the retort amounts to 0.05 of the marrow distilled. It is dark brown, heavy, and brilliant. It is incinerated with difficulty, and leaves an ash consisting of phosphate of lime, carbonate of lime, and some soda.

Marrow combines with alkalies and forms soap. Boiling alcohol and ether dissolve a small portion of it, which precipitates again as soon as the solution cools.

Composition.

Marrow, from the thigh bone of an ox, was found, by Berzelius, to be composed of the following substances:

Pure marrow	0.96
Skins and blood-vessels	0.01
Albumen	0.03
Gelatine	
Extractive	
Peculiar matter	
Water	
	1.00

From the preceding detail, it appears, that pure marrow is a species of fixed oil, possessing peculiar properties, and approaching somewhat to butter in its nature.

Sect. VIII. *Of Hair and Feathers.*

These substances cover different parts of animals, and are obviously intended by nature to protect them from the cold. For this, their softness and pliability, and the slowness with which they conduct heat, render them peculiarly proper.

Hair.

1. *Hair* is usually distinguished into various kinds, according to its size and appearance. The strongest and stiffest of all is called *bristle*; of this kind is the hair on the backs of hogs. When remarkably fine, soft, and pliable, it is called *wool*; and the finest of all is known by the name of *down*. But all these varieties resemble one another very closely in their composition.

Vauquelin has lately published a curious set of experiments on the analysis of human hair of various colours. Though hair is insoluble in boiling water, he obtained a solution by raising the temperature of the liquid in a Papin's digester. If the heat thus produced was too great, the hair was decomposed, and ammonia, carbonic acid, and an empyreumatic oil formed. Sulphureted hydrogen is always evolved, and its quantity increases with the heat. When hair is thus dissolved in water heated above the boiling point, the solution contains a kind of bituminous oil, which is deposited very slowly. This oil was black when the hair dissolved was black, but yellowish red when red hair was employed.

When the solution is filtered to get rid of this oil, the liquid which passes through is nearly colourless. Copious precipitates are formed in it by the infusion of nutgalls and oxymuriatic acid. Silver is blackened by it, and acetate of lead precipitated brown. Acids render it turbid, but the precipitate is re-dissolved, by adding these liquids in excess. Though very much concentrated by evaporation, it does not concrete into a jelly.

Water containing only four per cent. of potash dissolves hair, while hydrosulphuret of ammonia is evolved. If the hair be black, a thick dark-coloured oil, with some sulphur and iron, remains undissolved; if the hair be red, there remains a yellow oil, with some sulphur and an atom or two of iron. When acids are dropt into this solution, they throw down a white matter soluble in an excess of acid.

Sulphuric and muriatic acids become red when first poured on hair, and gradually dissolve it. Nitric acid turns hair yellow and dissolves it, while an oil separates, which is red or black according to the colour of the hair dissolved. The solution yields a great deal of oxalic acid, and contains, besides, bitter principle, iron, and sulphuric acid. Oxymuriatic acid first whitens hair, and then reduces it to a substance of the consistence of turpentine, and partly soluble in alcohol.

When alcohol is digested on black hair, it extracts from it two kinds of oil. The first, which is white, subsides in white shining scales as the liquor cools; the second is obtained by evaporating the alcohol. It has a greyish green colour, and at last becomes solid. From red hair alcohol likewise separates two oils; the first white as from black hair, and the other as red as blood. When the red hair is deprived of this oil, it becomes of a chesnut colour. Hence its red colour is obviously owing to the red oil.

When hair is incinerated, it yields iron and manganese, phosphate, sulphate, and carbonate of lime, muriate of soda, and a considerable portion of silica. The ashes of red hair contain less iron and manganese: those of white hair still less; but in them we find magnesia, which is wanting in the other varieties of hair. The ashes of hair do not exceed 0.015 of the hair.

Composition of black hair.

From the preceding experiments of Vauquelin, we learn that black hair is composed of the nine following substances:

1. An animal matter, constituting the greatest part.
2. A white solid oil, small in quantity.
3. A greyish green oil, more abundant.
4. Iron; state unknown.

5. Oxide of manganese.
6. Phosphate of lime.
7. Carbonate of lime, very scanty.
8. Silica.
9. Sulphur.

The colouring matter of hair appears from Vauquelin's experiments to be an oil. The oil is blackish green in black hair, red in red hair, and white in white hair. Vauquelin supposes that sulphureted iron contributes to the colour of dark hair; and ascribes to the presence of an excess of sulphur the property which white and red hair have of becoming black with the oxides of the white metals. The sudden change of colour in hair from grief, he thinks, is owing to the evolution of an acid.

Feathers.

2. *Feathers* seem to possess nearly the same properties with hair. Mr Hatchett has ascertained that the quill is composed chiefly of coagulated albumen. Though feathers were boiled for a long time in water, Mr Hatchett could observe no traces of gelatine.

Having given the preceding account of the solids which compose animal bodies, we proceed next to the fluid which circulates through living bodies, namely *blood;* and to the various *secretions* formed from the blood, either in order to answer some important purpose to the animal, or to be evacuated as useless, that the blood thus purified may be more proper for answering the ends for which it was destined. Many of these substances have been examined with more care by chemists than the animal solids.

Sect. IX. *Of Blood.*

Blood. Its properties.

Blood is a well known fluid, which circulates in the veins and arteries of the more perfect animals. It is of a red colour, has a considerable degree of consistency, and an unctuous feel, as if it contained a quantity of soap. Its taste is slightly saline, and it has a peculiar smell.

The specific gravity of human blood is, at a medium, 1.0527.

When blood, after being drawn from an animal, is allowed to remain for some time at rest, it very soon coagulates into a solid mass of the consistence of curdled milk. This mass gradually separates into two parts; one of which is fluid, and is called *serum;* the other, the coagulum, has been called *cruor,* because it alone retains the red colour which distinguishes blood. This separation is very similar to the separation of curdled milk into curds and whey.

Serum.

1. The serum is of a light greenish yellow colour; it has the taste, smell, and feel of the blood, but its consistence is not so great. Its mean specific gravity is about 1.0287. It converts syrup of violets to a green, and therefore contains an alkali. On examination, Rouelle found that it owes this property to a portion of soda. When heated to the temperature of 156°, the serum coagulates, as Harvey first discovered. It coagulates also when boiling water is mixed with it; but if serum be mixed with six parts of cold water, it does not coagulate by heat. When thus coagulated, it has a greyish white colour, and is not unlike the boiled white of an egg. If the coagulum be cut into small pieces, a muddy fluid may be squeezed from it, which has been termed the *serosity.* After the separation of this fluid, if the residuum be carefully washed in boiling water and examined, it will be found to possess all the properties of coagulated *albumen.* The serum, therefore, contains a considerable proportion of albumen. Hence its coagulation by heat, and the other phenomena which albumen usually exhibits.

If the coagulated serum be heated in a silver vessel, the surface of the silver becomes black, being converted into a sulphuret. Hence it is evident, that it contains sulphur; and Proust has ascertained, that it is combined with ammonia in the state of a hydrosulphuret.

If serum be mixed with twice its weight of water, and, after coagulation by heat, the albumen be separated by filtration, and the liquid be slowly evaporated till it is considerably concentrated, a number of crystals are deposited when the liquid is left standing in a cool place. These crystals, first examined by Rouelle, consist of carbonate of soda, muriate of soda, besides phosphate of soda and phosphate of lime. The soda exists in the blood in a caustic state, and seems to be combined with the gelatine and albumen. The carbonic acid combines with it during evaporation.

Cruor.

2. The cruor, or *clot* as it is sometimes called, is of a red colour, and possesses considerable consistence. Its mean specific gravity is about 1.245. If this cruor be washed carefully, by letting a small jet of water fall upon it till the water runs off colourless, it is partly dissolved, and partly remains upon the searce. Thus it is separated into two portions: namely, 1. A white, solid, elastic substance, which has all the properties of *fibrin;* 2. The portion held in solution by the water, which consists of the colouring matter, not however in a state of purity, for it is impossible to separate the cruor completely from the serum.

Bucquet proved that this watery solution contained albumen and iron. Menghini had ascertained, that if blood be evaporated to dryness by a gentle heat, a quantity of iron may be separated from it by the magnet. The quantity which he obtained was considerable: according to him, the blood of a healthy man contains above two ounces of it. Now, as neither the serum nor the fibrin extracted from the cruor contains iron, it follows of course, that the water holding the colouring matter in solution must contain the whole of that metal.

This watery solution gives a green colour to syrup of violets. When exposed to the air, it gradually deposites flakes, which have the properties of albumen. When heated, a brown-coloured scum gathers on its surface. If it be evaporated to dryness, and then mixed with alcohol, a portion is dissolved, and the alcoholic solution yields by evaporation a residuum, which lathers like soap in water, and tinges vegetable blues green; the acids occasion a precipitate from its solution. This substance is a compound of albumen and soda. Thus we see that the watery solution contains albumen, iron, and soda.

Fourcroy and Vauquelin have ascertained, that the iron is combined with phosphoric acid, and in the state of subphosphate of iron; thus confirming an opinion which had been maintained by Sage, and announced as a fact by Gren.

Brande has lately shown, that the colouring matter of the blood is of an animal nature. He has proved, that it may be advantageously used as a dye-stuff.

Such are the properties of blood, as far as they have been hitherto ascertained by experiment. We have seen that it contains the following ingredients:

1. Water.
2. Fibrin.
3. Albumen.
4. Hydrosulph. of ammonia.
5. Soda.
6. Subphosphate of iron.
7. Muriate of soda.
8. Phosphate of soda.
9. Phosphate of lime.

Besides benzoic acid, which has been detected by Proust.

SECT. X. *Of Milk.*

Milk.

Milk is a fluid secreted by the female of all those animals denominated *mammalia*, and intended evidently for the nourishment of her offspring.

The milk of every animal has certain peculiarities which distinguish it from every other milk. But the animal whose milk is most made use of by man as an article of food, and with which, consequently, we are best acquainted, is the *cow*. Chemists, therefore, have made choice of cow's milk for their experiments.

Properties of cow's milk.

Milk is an opaque fluid, of a white colour, a slight peculiar smell, and a pleasant sweetish taste. When newly drawn from the cow, it has a taste very different from that which it acquires, after it has been kept for some hours. It reddens vegetable blues.

When milk is allowed to remain for some time at rest, there collects on its surface a thick unctuous yellowish-coloured substance, known by the name of cream.

After the cream is separated, the milk which remains is much thinner than before, and it has a bluish white colour. If it be heated to the temperature of 100°, and a little *rennet*, which is water digested with the inner coat of a calf's stomach, and preserved with salt, be poured into it, coagulation ensues; and if the coagulum be broken, the milk very soon separates into two substances; a solid white part known by the name of *curd*, and a fluid part called *whey*. Thus we see that milk may be easily separated into three parts; namely, *cream*, *curd*, and *whey*.

Cream.

1. Cream is of a yellow colour, and its consistence increases gradually by exposure to the atmosphere. In three or four days it becomes so thick, that the vessel which contains it may be inverted without risking any loss. In eight or ten days more, its surface is covered over with mucors and byssi, and it has no longer the flavour of cream, but of very fat cheese.

Cream possesses many of the properties of an oil. It is specifically lighter than water; it has an unctuous feel, stains cloths precisely in the manner of oil; and if it be kept fluid, it contracts at last a taste which is very analogous to the rancidity of oils. These properties are sufficient to show us that it contains a quantity of oil; but this oil is combined with a part of the curd, and mixed with some serum. Cream, then, is composed of a peculiar oil, curd, and serum. The oil may be easily obtained separate, by agitating the cream for a considerable time. This process, known to every body, is called *churning*. After a certain time, the cream separates into two portions: one fluid, and resembling creamed milk; the other solid, and called *butter*.

Butter.

Butter is of a yellow colour, possesses the properties of an oil, and mixes readily with other oily bodies. When heated to the temperature of 96° it melts, and becomes transparent; if it be kept for some time melted, some curd and water or whey separate from it, and it assumes exactly the appearance of oil. But this process deprives it in a great measure of its peculiar flavour.

Butter may be obtained, by agitating cream newly taken from milk, or even by agitating milk newly drawn from the cow. But it is usual to allow cream to remain for some time before it is churned. Now cream, by standing, acquires a sour taste; butter, therefore, is commonly made from sour cream. When very sour cream is churned, every one must have perceived, that the butter milk, after the churning, is not nearly so sour as the cream had been. The butter, in all cases, is perfectly sweet; consequently the acid which had been evolved, has in a great measure disappeared during the progress of churning. It has been ascertained that cream may be churned, and butter obtained, though the contact of atmospheric air be excluded. On the other hand, it has been affirmed, that when cream is churned in contact with air, it absorbs a considerable quantity of it.

In many cases, there is a considerable extrication of gas during the churning of water. From the phenomena, it can scarcely he doubted that this acid is carbonic acid. See BUTTER.

Curd.

2. Curd, which may be separated from creamed milk by rennet, has many of the properties of coagulated albumen. It is white and solid; and when all the moisture is squeezed out, it has a good deal of brittleness. It is insoluble in water; but pure alkalies and lime dissolve it readily, especially when assisted by heat; and when fixed alkali is used, a great quantity of ammonia is emitted during the solution. The solution of curd in soda is of a red colour, at least if heat be employed, owing probably to the separation of charcoal from the curd by the action of the alkali. The matter dissolved by the alkali may be separated from it by means of an acid; but it has lost all the properties of curd. It is of a black colour, melts like tallow by the application of heat, leaves oily stains on paper, and never acquires the consistence of curd. Its constituents, according to the experiments of Thenard and Gay-Lussac, are as follows:

Carbon	59.781
Oxygen	11.409
Hydrogen	7.429
Azote	21.381
	100

Cheese.

Curd, as is well known, is used in making *cheese*, and the cheese is the better the more it contains of cream, or of that oily matter which constitutes cream. It is well known to cheesemakers, that the goodness of it depends in a great measure on the manner of separating the whey from the curd. If the milk be much heated, the coagulum broken in pieces, and the whey forcibly separated, as is the practice in many parts of Scotland, the cheese is scarce good for any thing; but the whey is delicious, especially the last squeezed out whey, and butter may be obtained from it in considerable quantity:—a full proof that nearly the whole creamy part of the milk has been separated with the whey. Whereas if the milk be not too much heated, (about 100° is sufficient,) if the coagulum be allowed to remain unbroken, and the whey be separated by very slow and gentle pressure, the cheese is excellent; but the whey is almost transparent, and nearly colourless.

Good cheese melts at a moderate heat; but bad cheese, when heated, dries, curls, and exhibits all the phenomena of burning horn. From this it is evident, that good cheese contains a quantity of the peculiar oil which constitutes the distinguishing characteristic of cream; hence its flavour and smell. Proust has found in cheese an acid which he calls the *caseic* acid, to which he ascribes several of the peculiar properties of cheese. See DAIRY.

Whey.

3. Whey, after being filtered, to separate a quantity of curd which still continues to float through it, is a thin pellucid fluid, of a yellowish green colour, and pleasant sweetish taste, in which the flavour of milk may be distinguished. It always contains some curd; but nearly the whole may be separated by keeping the whey for some time boiling; a thick white scum gathers on the surface, which in Scotland is known by the name of *float whey*. When this scum, which consists of the curdy part, is carefully separated, the whey, after being allow-

ed to remain at rest for some hours, to give the remainder of the curd time to precipitate. is decanted off almost as colourless as water, and scarcely any of the peculiar taste of milk can be distinguished in it. If it be now slowly evaporated, it deposites at last a number of white-coloured crystals, which are *sugar of milk*. Toward the end of the evaporation, some crystals of muriate of potash and of muriate of soda make their appearance. According to Scheele, it contains also a little phosphate of lime, which may be precipitated by ammonia.

The recent experiments of Fourcroy and Vauquelin, Thenard, and Bouillon La Grange, have added considerably to our knowledge of the constituents of whey. It always reddens vegetable blues, containing a portion of acetic acid. The lactic acid of Scheele is nothing else than this acid holding an animal matter in solution. It contains likewise some phosphate of magnesia and phosphate of iron, as Fourcroy and Vauquelin have discovered. Sulphate of potash, likewise, and a peculiar extractive matter, have been separated from it.

Composition of cow's milk.

Thus we see that cow's milk is composed of the following ingredients:

1. Water.
2. Oil.
3. Curd.
4. Extractive.
5. Sugar of milk.
6. Acetic acid.
7. Muriate of soda.
8. Muriate of potash.
9. Sulphate of potash.
10. Phosphate of lime.
11. Phosphate of magnesia.
12. Phosphate of iron.

The milk of all other animals, as far as it has hitherto been examined, consists nearly of the same ingredients; but there is a very great difference in their proportion.

Sect. XI. *Of Saliva.*

Saliva.

The fluid secreted in the mouth, which flows in considerable quantity during a repast, is known by the name of *saliva*.

Its properties.

Saliva is a limpid fluid like water, but much more viscid. It has neither smell nor taste. Its specific gravity, according to Hamberger, is 1.0167; according to Siebold, 1.080. When agitated, it froths like all other adhesive liquids; indeed it is usually mixed with air, and has the appearance of froth.

It neither mixes readily with water nor oil; but by trituration in a mortar, it may be so mixed with water as to pass through a filter. It has a great affinity for oxygen, absorbs it readily from the air, and gives it out again to other bodies.

When boiled in water, a few flakes of albumen precipitate. From the experiments of Dr Bostock, we learn that this albumen is not in a state of solution. It is separated by the filter, and subsides of its own accord when the liquid is diluted with water. In his analysis, this coagulated albumen amounted to 0.4 of the solid matter contained in the saliva examined.

When saliva is evaporated, it swells exceedingly, and leaves behind it a thin brown coloured crust; but if the evaporation be conducted slowly, small cubic crystals of muriate of soda are formed. The viscidity of saliva, the property which it has of absorbing oxygen, and of being inspissated, announce the presence of mucus as a component part. This is fully confirmed by the effect of neutral acetate of lead, which produces a copious precipitate in saliva. Dr Bostock considers the mucus as constituting about one-half of the solid contents of saliva.

When saliva is distilled in a retort, it froths very much; 100 parts yield 80 parts of water nearly pure, then a little carbonate of ammonia, some oil, and an acid, which perhaps is the prussic. The residuum amounts to about 1.56 part, and is composed of muriate of soda, phosphate of soda, and phosphate of lime.

The acids and alcohol inspissate saliva; the alkalies disengage ammonia; oxalic acid precipitates lime; and the nitrates of lead, mercury, and silver, precipitate phosphoric and muriatic acids.

From these facts, it follows that saliva, besides water, which constitutes at least four-fifths of its bulk, contains the following ingredients:

Composition.

1. Mucilage.
2. Albumen.
3. Muriate of soda.
4. Phosphate of soda.
5. Phosphate of lime.
6. Phosphate of ammonia.

But it cannot be doubted, that, like all the other animal fluids, it is liable to many changes from disease, &c. Brugnatelli found the saliva of a patient labouring under an obstinate venereal disease impregnated with oxalic acid.

Sect. XII. *Of Bile.*

Bile.

Bile is a liquid of a yellowish green colour, an unctuous feel, bitter taste, and peculiar smell, which is secreted by the liver; and, in most animals, considerable quantities of it are usually found collected in the gall bladder.

Ox bile.

1. Ox bile is a liquid of a yellowish green, and sometimes of a deep green colour. Its taste is very bitter, but at the same time sweetish. Its smell is feeble, but peculiar and disagreeable. It does not act on vegetable blues. Its consistence varies very much. Sometimes it is a thin mucilage; sometimes very viscid and glutinous; sometimes it is perfectly transparent; and sometimes it contains a yellow-coloured matter, which precipitates when the bile is diluted with water.

When an acid is added to bile, even in a minute quantity, it acquires the property of reddening vegetable blues. The addition of a little more acid occasions a precipitate, and sulphuric acid occasions a greater precipitate than any other acid. This precipitate consists of a yellow-coloured matter often visible in bile, and which is insoluble in water. It contains also a little resin, which gives it a bitter taste. Acids do not throw down the whole resin from bile. Yet if the resin be dissolved in soda, it is readily precipitated by all the acids; a proof that the resin is not kept in solution in bile by soda.

When superacetate of lead is poured into bile, a copious white precipitate falls, consisting of the resin combined with the oxide of lead. The superacetate of commerce does not readily throw down the whole resin; but if eight parts of common sugar of lead and one part of litharge be united together by digestion in water, a salt is formed, which readily throws down the whole of the resin. If the precipitate be treated with diluted nitric acid, the lead is separated, and the resin remains behind in a state of purity. It is a green-coloured bitter tasted substance, possessing most of the properties of resins. It has been already described in the preceding Section. One hundred parts of bile contain about three parts of resin.

If acetate of lead be poured into bile thus deprived of its resin by the superacetate, a new and more copious precipitate falls, consisting of the oxide of lead united to a peculiar substance, which gives bile most of its characters. This substance was first described in detail by Thenard, who has given it the name of *picromel*. The compound, consisting of oxide of lead and picromel, is soluble in acetic acid. If a current of sulphureted hydrogen gas be passed through the solution, the lead is separated; and by filtering and evaporating the liquid to dryness, the picromel is obtained in a separate state. When bile, mixed with muriatic acid and filtered, is set aside for some months in an open vessel, I have seen the picromel separate of its own accord. It is a white solid substance in small globules. It has a sweet, and at the same time an acrid taste, and is often somewhat bitter from retaining a portion of the resin. It facilitates the solution of resin in water: three parts of picromel and one part of resin dissolve in water.

By evaporating a quantity of bile to dryness, calcining it, and proceeding in the usual way, Thenard ascertained the proportion of salts which it contained. The following was the result of his analysis of 800 parts of bile:

Composition.

700.0 water.
24.0 resin.
60.3 picromel.
4.5 yellow matter.
4.0 soda.
2.0 phosphate of soda.
3.2 muriate of soda.
0.8 sulphate of soda.
1.2 phosphate of lime.
oxide of iron, a trace.

800.0

Bile of the calf, dog, &c.

2. Such are the properties and the constituents of ox bile, as far as they have been examined by Thenard. From the experiments of the same chemist, it appears that the bile of the calf, the dog, the sheep, and the cat, resemble that of the ox exactly, both in their properties and their constituents.

Bile of the sow.

3. The bile of the sow differs entirely from that of all these animals. It contains neither albumen, nor animal matter, nor picromel, but is merely a soap, as it contains a great quantity of resin and of soda, and is decomposed with facility by all the acids, even by vinegar. It contains traces also of several salts; but Thenard did not ascertain their nature.

Bile of the hen, &c.

4. The bile of the common hen, of the turkey, and the duck, has a good deal of resemblance to that of quadrupeds. But it differs in the following particulars: 1. It contains a considerable quantity of albumen; 2. The picromel has no sensible sweet taste, but is very acrid and bitter; 3. It contains very little soda; 4. The resin is not precipitated by common superacetate of lead; but superacetate, boiled with one-fourth of its weight of litharge, occasions it to precipitate.

Bile of the thornback and salmon.

5. The bile of the thornback and salmon is yellowish white. When evaporated, it leaves a matter which has a very sweet and slightly acrid taste. It appears to contain no resin. The bile of the carp and the eel is very green, very bitter, contains little or no albumen, but yields soda, resin, and a sweet acrid matter similar to that which may be obtained from salmon bile.

Human bile.

6. Human bile differs considerably from that of all other animals examined. Its taste is not very bitter. It is seldom completely liquid, but usually contains some yellow matter suspended in it. When evaporated to dryness, it leaves a brown matter amounting to about $\frac{1}{11}$th of the original weight. All the acids decompose human bile, and throw down a copious precipitate consisting of albumen and resin. The following were the proportions of the constituents obtained by Thenard from 1100 parts of human bile.

Composition.

1000.0 water.
from 2 to 10 yellow insoluble matter.
yellow matter in solution, a trace.
42.0 albumen.
41.0 resin.
5.6 soda.
4.5 phosphate of soda, sulphate of soda, muriate of soda, phosphate of lime, oxide of iron.

Sect. XIII. *Of the Cerumen of the Ear.*

Cerumen of the ear.

Cerumen is a viscid yellow-coloured liquid secreted by the glands of the auditory canal, which gradually becomes concrete by exposure to the air.

Its properties.

It has an orange yellow colour, and a bitter taste. When slightly heated upon paper, it melts, and stains the paper like an oil; at the same time it emits a slightly aromatic odour. On burning coals it softens, and emits a white smoke, which resembles that given out by burning fat; it afterwards melts, swells, becomes dark coloured, and emits an ammoniacal and empyreumatic odour. A light coal remains behind.

When agitated in water, cerumen forms a kind of emulsion, which soon putrefies, depositing at the same time white flakes.

Alcohol, when assisted by heat, dissolves five-eighths of the cerumen; the three-eighths which remain behind have the properties of albumen, mixed however with a little oily matter. When the alcohol is evaporated, it leaves a deep orange residuum of a very bitter taste, having a smell and a consistence analogous to turpentine. It melts when heated, evaporates in a white smoke without leaving any residuum, and, in short, resembles very strongly the *resin of bile*. Ether also dissolves this oily body; but it is much less bitter, and much lighter coloured. When the albuminous part of cerumen is burnt, it leaves traces of soda and of phosphate of lime. From these facts, Vauquelin considers cerumen as composed of the following substances:

Composition.

1. Albumen.
2. An inspissated oil.
3. A colouring matter.
4. Soda.
5. Phosphate of lime.

Sect. XIV. *Of Tears and Mucus.*

Tears.

1. The liquid called tears is transparent and colourless like water; it has scarcely any smell, but its taste is always perceptibly salt. Its specific gravity is somewhat greater than that of distilled water. It gives to paper stained with the juice of the petals of mallows or violet a permanently green colour, and therefore contains a fixed alkali. It unites with water, whether cold or hot, in all proportions. Alkalies unite with it readily, and render it more fluid. The mineral acids produce no apparent change upon it. Exposed to the air, this liquid gradually evaporates, and becomes thicker. When nearly reduced to a state of dryness, a number of cubic crystals form in the midst of a kind of mucilage. These crystals possess the properties of muriate of soda; but they tinge vegetable blues green, and therefore contain an excess of soda. The mucilaginous matter acquires a yellowish colour as it dries.

When alcohol is poured into this liquid, a mucilaginous matter is precipitated in the form of large white flakes. The alcohol leaves behind it, when evaporated, traces of muriate of soda and soda. The residuum which remains behind, when inspissated tears are burnt in the open air, exhibits some traces of phosphate of lime, and phosphate of soda.

Thus it appears, that tears are composed of the following ingredients:

1. Water.
2. Mucus.
3. Muriate of soda.
4. Soda.
5. Phosphate of lime.
6. Phosphate of soda.

The saline parts amount only to about 0.01 of the whole, or probably not so much.

Mucus of the nose.

2. The mucus of the nose has also been examined by Fourcroy and Vauquelin. They found it composed of precisely the same ingredients with the tears. As this fluid is more exposed to the action of the air than the tears, in most cases its mucilage has undergone less or more of that change which is the consequence of the absorption of oxygen. Hence the reason of the greater viscidity and consistence of the mucus of the nose; hence also the great consistence which it acquires during colds, where the action of the atmosphere is assisted by the increased action of the parts.

3. As to the mucus which lubricates the alimentary canal, the trachea, the bronchiæ, the urethra, and all the different cavities of the body, nobody has hitherto subjected it to analysis, because it cannot be obtained in sufficient quantity. It is viscid, and no doubt contains a mucilaginous substance, similar to that contained in the saliva, the tears, and the mucus of the nose; as, like these liquids, it is liable to become much more thick by exposure to the air.

SECT. XV. *Liquor of the Pericardium.*

Liquor of the pericardium.

This is a liquor which lubricates the heart. It has been lately examined by Dr Bostock, having been obtained from the pericardium of a boy who had died suddenly.

Its properties.

It had the colour and appearance of the serum of the blood. Evaporated to dryness, it left a residue amounting to $\frac{1}{11}$th of its weight. When exposed to the heat of boiling water, it became opake and thready. It was copiously precipitated by oxymuriate of mercury before boiling; but when boiled, evaporated to dryness, and redissolved, the solution was not affected by oxymuriate of mercury. These experiments show us that it contained albumen. When saturated with oxymuriate of mercury, infusion of galls produced no effect, indicating the absence of gelatine. It was copiously precipitated by neutral acetate of lead, even after being boiled to dryness, and the residue re-dissolved in water. Nitrate of silver indicated the presence of muriatic acid. Dr Bostock, from his experiments, considers it composed of

Composition.

Water	92.0
Albumen	5.5
Mucus	2.0
Muriate of soda	0.5
	100.0

SECT. XVI. *Of the Humours of the Eye.*

Humours of the eye.

The eye is one of the most delicate and complicated organs in the body; at the same time its structure, and the uses of its parts, are better understood than almost any of the other instruments of sensation. It is composed of several concentric coats, which have not been chemically examined; but, from the experiments of Hatchett on similar substances, we may consider it as probable that they possess the properties of coagulated albumen. The internal part of the eye is chiefly filled with three transparent substances, which have been called *humours* by anatomists; namely, 1. The *aqueous humour*, immediately behind the cornea; 2. The *crystalline humour*, or *lens*; and, 3. The *vitreous humour*, behind the lens, and occupying the greatest part of the eye.

1. The aqueous humour of the eye of the sheep is a clear transparent liquid like water, which has very little smell or taste when fresh. Its specific gravity is 1.0090 at the temperature of 60°. It appears to be water slightly impregnated with the following substances:

1. Albumen. 2. Gelatine. 3. Muriate of soda.

2. The vitreous matter possesses the very same properties as the aqueous; even its specific gravity is the same, or only a very little greater.

3. The crystalline lens is solid: densest in the centre, and becoming less solid towards the circumference. It is composed of concentric coats, and is transparent. Its specific gravity is 1.1000. When fresh, it has little taste. It putrefies very rapidly.

It is almost completely soluble in water. The solution is partly coagulated by heat, and gives a copious precipitate with tannin, both before the coagulation and after it. It gives no traces of muriatic acid. Hence it is composed of albumen and gelatine united to water. According to Nicholas, the quantity of gelatine diminishes as we approach the centre of the lens, where it is very small. He detected phosphate of lime likewise in every part of the lens.

The humours of the human eye are composed of the same ingredients as those of the sheep; the only perceptible difference consists in their specific gravity. The specific gravity of the human aqueous and vitreous humours is 1.0053; that of the crystalline 1.0790.

The humours of the eyes of oxen resemble those of the sheep in their composition. The specific gravity of the aqueous and vitreous humours is 1.0088; that of the crystalline 1.0765.

SECT. XVII. *Of Sinovia.*

Sinovia.

Within the capsular ligament of the different joints of the body there is contained a peculiar liquid, intended evidently to lubricate the parts, and to facilitate their motion. This liquid is known among anatomists by the name of *sinovia*.

Its properties.

The sinovia of the ox, when it has just flowed from the joint, is a viscid semitransparent fluid, of a greenish white colour, and a smell not unlike frog-spawn. It very soon acquires the consistence of jelly; and this happens equally whether it be kept in a cold or a hot temperature, whether it be exposed to the air or excluded from it. This consistence does not continue long; the sinovia soon recovers again its fluidity, and at the same time deposites a thready-like matter.

Sinovia mixes readily with water, and imparts to that liquid a great deal of viscidity. The mixture froths when agitated; becomes milky when boiled, and deposites some pellicles on the sides of the dish; but its viscidity is not diminished.

When alcohol is poured into sinovia, a white substance precipitates, which has all the properties of albumen. One hundred parts of sinovia contain 4.52 of albumen. The liquid still continues as viscid as ever; but if acetic acid be poured into it, the viscidity disappears altogether, the liquid becomes transparent, and deposites a quantity of matter in white threads, which possesses the following properties: 1. It has the colour, smell, taste, and elasticity of vegetable gluten. 2. It is soluble in concentrated acids and pure alkalies. 3. It is soluble in cold water; the solution froths. Acids and alcohol precipitate the fibrous matter in flakes. One hundred parts of sinovia contain 11.86 of this matter.

Margueron found that 100 parts of sinovia contained about 0.71 of soda.

When sinovia is exposed to a dry atmosphere, it gradually evaporates, and a scaly residuum remains, in which cubic crystals, and a white saline efflorescence, are apparent. The cubic crystals are muriate of soda. One hundred parts of sinovia contain 1.75 of this salt. The saline efflorescence is carbonate of soda.

Composition.

From the analysis of Mr Margueron, it appears that sinovia is composed of the following ingredients:

11.86	fibrous matter,
4.52	albumen,
1.75	muriate of soda,
.71	soda,
.70	phosphate of lime,
80.46	water.
100.00	

SECT. XVIII. *Of Semen.*

Semen.

The peculiar liquid secreted in the testes of males, and destined for the impregnation of females, is known by the name of *semen*.

Semen, when newly ejected, is evidently a mixture of two different substances; the one fluid and milky, which is supposed to be secreted by the prostate gland; the other, which is considered as the true secretion of the testes, is a thick mucilaginous substance, in which numerous white shining filaments may be discovered. It has a slight disagreeable odour, an acrid irritating taste, and its specific gravity is greater than that of water. When rubbed in a mortar, it becomes frothy, and of the consistence of pomatum, in consequence of its enveloping a great number of air bubbles. It converts paper stained with the blossoms of mallows or violets to a green colour, and consequently contains an alkali.

As the liquid cools, the mucilaginous part becomes transparent, and acquires greater consistency; but in about twenty minutes after its emission, the whole becomes perfectly liquid. This liquefaction is not owing to the absorption of moisture from the air, for it loses instead of acquiring weight during its exposure to the atmosphere; nor is it owing to the action of the air, for it takes place equally in close vessels.

When oxymuriatic acid is poured into semen, a number of white flakes precipitate, and the acid loses its peculiar odour. These flakes are insoluble in water, and even in acids. If the quantity of acid be sufficient, the semen acquires a yellow colour. Thus it appears that semen contains a mucilaginous substance analogous to that of the tears, which coagulates by absorbing oxygen. Mr Vauquelin obtained from 100 parts of semen six parts of this mucilage.

When semen is exposed to the air about the temperature of 60°, it becomes gradually covered with a transparent pellicle, and in three or four days deposites small transparent crystals, often crossing each other in such a manner as to represent the spokes of a wheel. These crystals, when viewed through a microscope, appear to be four sided prisms, terminated by very long four-sided pyramids. They may be separated by diluting the liquid with water, and decanting it off. They have all the properties of phosphate of lime. If, after the appearance of these crystals, the semen be still allowed to remain exposed to the atmosphere, the pellicle on its surface gradually thickens, and a number of white round bodies appear on different parts of it. These bodies also are phosphate of lime, prevented from crystallizing regularly by the too rapid abstraction of moisture. Mr Vauquelin found that 100 parts of semen contain three parts of phosphate of lime. If, at this period of the evaporation, the air becomes moist, other crystals appear in the semen, which have the properties of carbonate of soda. The evaporation does not go on to complete exsiccation, unless at the temperature of 77°, and when the air is very dry. When all the moisture is evaporated, the semen has lost 0.9 of its weight; the residuum is semitransparent like horn, and brittle.

Composition.

Thus it appears that semen is composed of the following ingredients:

90	water.
6	mucilage.
3	phosphate of lime.
1	soda.
100	

SECT. XIX. *Of Animal Poisons.*

Animal poisons.

Several animals are furnished with liquid juices of a poisonous nature, which, when poured into fresh wounds, occasion the disease or death of the wounded animal. Serpents, bees, scorpions, spiders, are well known examples of such animals. The chemical properties of these poisonous juices deserve peculiar attention; because it is only from such an investigation that we can hope to explain the fatal changes which they induce on the animal economy, or to discover an antidote sufficiently powerful to counteract their baneful influence. Unfortunately the task is difficult, and perhaps surpasses our chemical powers. For the progress already made in the investigation, we are indebted almost entirely to the labours of Fontana.

Poison of the viper,

1. The poison of the viper is a yellow liquid, which lodges in two small vesicles in the animal's mouth. These communicate by a tube with the crooked fangs, which are hollow, and terminate in a small cavity. When the animal bites, the vesicles are squeezed, and the poison is forced through the fangs into the wound.

This poisonous juice occasions the fatal effects of the viper's bite. It has a yellow colour, has no taste; but when applied to the tongue occasions numbness. It has the appearance of oil before the microscope, but it unites readily with water. It produces no change on vegetable blues.

When exposed to the open air, the watery part gradually evaporates, and a yellowish-brown substance remains, which has the appearance of gum arabic. In this state it feels viscid like gum between the teeth; it dissolves readily in water, but not in alcohol; and alcohol throws it down in a white powder from water. Neither acids nor alkalies have much effect upon it. It does not unite with volatile oils nor sulphuret of potash. When heated it does not melt, but swells, and does not inflame till it has become black. These properties are similar to the properties of gum, and indicate the gummy nature of this poisonous substance. Fontana made a set of experiments on the dry poison of the viper, and a similar set on gum arabic, and obtained the same results.

From the late observations of Dr Russel, there is reason to believe that the poisonous juices of the other serpents are similar in their properties to those of the viper.

This striking resemblance between gums and the poison of the viper, two substances of so opposite a nature in their effects upon the living body, is a humiliating proof of the small progress we have made in the chemical knowledge of these intricate substances. The poison of the viper, and of serpents in general, is most hurtful when mixed with the blood. Taken into the stomach it kills if the quantity be considerable. Fontana has ascertained that its fatal effects are proportional to its quantity, compared with the quantity of the blood. Hence the danger diminishes as the size of the animal increases. Small birds and quadrupeds die immediately when they are bitten by a viper; but to a full-sized man the bite seldom proves fatal.

Ammonia has been proposed as an antidote to the bite of the viper. It was introduced in consequence of the theory of Dr Mead, that the poison was of an acid nature. The numerous trials of that medicine by Fontana robbed it of all its celebrity; but it has been lately revived and recommended by Dr Ramsay as a certain cure for the bite of the rattlesnake.

Bee and wasp,

2. The venom of the bee and the wasp is also a liquid contained in a small vesicle, forced through the hollow tube of the sting into the wound inflicted by that instrument. From the experiments of Fontana, we learn that it bears a striking resemblance to the poison of the viper. That of the bee is much longer in drying when exposed to the air than the venom of the wasp.

Scorpion,

3. The poison of the scorpion resembles that of the viper also. But its taste is hot and acrid, which is the case also with the venom of the bee and the wasp.

And spider tribe.

4. No experiments upon which we can rely have been made upon the poison of the spider tribe. From the rapidity with which these animals destroy their prey, and even one another, we cannot doubt that their poison is sufficiently virulent.

Sect. XX. *Of Sweat.*

Sweat.

A quantity of matter is constantly emitted from the skin; this matter is invisible, and is distinguished by the name of *perspiration*. Several experiments were made by Lavoisier and Seguin to ascertain its amount. Mr Cruickshanks made numerous trials to determine its nature, and it has been lately subjected to a chemical examination by Thenard.

1. Mr Cruickshanks put his hand into a glass vessel, and luted its mouth at his wrist by means of a bladder. The interior surface of the vessel became gradually dim, and drops of water trickled down. By keeping his hand in this manner for an hour, he collected 30 grains of a liquid, which possessed all the properties of pure water. On repeating the same experiment at nine in the evening (thermometer 62°,) he collected only 12 grains. The mean of these is 21 grains. But as the hand is more exposed than the trunk of the body, it is reasonable to suppose that the perspiration from it is greater than that from the hand. Let us therefore take 30 grains per hour as the mean; and let us suppose, with Mr Cruickshanks, that the hand is $\frac{1}{60}$th of the surface of the body: The perspiration in an hour would amount to 1880 grains, and in 24 hours to 43,200 grains, or seven pounds six ounces troy. This is almost double of the quantity ascertained by Lavoisier and Seguin. Hence we may conclude that more matter is perspired through the hand than the other parts of the body, provided Mr Cruickshank's estimate of the ratio between the surface of the hand and body be not erroneous.

He repeated the experiment again after hard exercise, and collected in an hour 48 grains of water. He found also, that this aqueous vapour pervaded his stocking without difficulty; and that it made its way through a shamoy leather glove, and even through a leather boot, though in a much smaller quantity than when the leg wanted that covering.

2. Besides water, it cannot be doubted that *carbon* is also emitted from the skin; but in what state, the experiments hitherto made do not enable us to decide. Mr Cruickshanks found that the air of the glass vessel in which his hand and foot had been confined for an hour contained carbonic acid gas; for a candle burned dimly in it, and it rendered limewater turbid.

3. Besides water and carbon, or carbonic acid gas, the skin emits also a particular odorous substance. That every animal has a peculiar smell, is well known: the dog can discover his master, and even trace him to a distance, by the scent. A dog, chained some hours after his master had set out on a journey of some hundred miles, followed his footsteps by the smell, and found him on the third day in the midst of a crowd. But it is needless to multiply instances of this fact, they are too well known to every one. Now this smell must be owing to some peculiar matter which is constantly emitted; and this matter must differ somewhat either in quantity or some other property, as we see that the dog easily distinguishes the individual by means of it. Mr Cruickshanks has made it probable that this matter is an oily substance; or at least that there is an oily substance emitted by the skin. He wore repeatedly, night and day, for a month, the same vest of fleecy hosiery during the hottest part of the summer. At the end of this time he always found an oily substance accumulated in considerable masses on the nap of the inner surface of the vest, in the form of black tears. When rubbed on paper, it makes it transparent, and hardens on it like grease. It burns with a white flame, and leaves behind it a charry residuum.

4. Berthollet has observed the perspiration acid; and he has concluded that the acid which is present is the phosphoric: but that has not been proved. Indeed the late experiments of Thenard have proved that the acid in *perspired matter* is not the phosphoric, but the acetic. He employed the method practised by Mr Cruickshanks to collect this matter. Different persons wore clean flannel waistcoats next their skin for ten days, the waistcoats had been first washed with soap, then in pure water, then in water acidulated with muriatic acid, and lastly in a great quantity of pure wate. He steeped the waistcoats in hot distilled water, and thus separated from them the perspired matter. The liquid was put into a retort, and concentrated to the consistence of a syrup. The liquid which came over had a disagreeable smell, and reddened infusion of litmus. Kept in an open vessel it retained its transparency, but lost its odour. The residue in the retort had no smell. It was strongly acid, and tasted distinctly of common salt, while at the same time an acrid and hot flavour could be distinguished. When evaporated to dryness and strongly heated, the acid which it contained was dissipated or destroyed, and the residue consisted of common salt, charcoal, and minute traces of phosphate of lime, and oxide of iron. The same destruction of the acid took place if it was previously saturated with potash before it was heated to redness, and in that case the potash was converted into a carbonate. When saturated with an alkali, and distilled along with phosphoric acid, it yielded an acid which possessed all the characters of the acetic.

5. The small quantity of animal matter which Thenard found in the perspired matter, possessed characters which induced him to consider it as similar to gelatine in its nature.

SECT. XXI. *Of Urine.*

Urine.

Fresh urine differs considerably in its appearance, according to the state of the person, and the time at which it is voided. In general, healthy urine is a transparent liquid of a light amber colour, an aromatic odour resembling that of violets, and a disagreeable bitter taste. Its specific gravity varies, according to Mr Cruickshanks, from 1.005 to 1.033. When it cools, the aromatic smell leaves it, and is succeeded by another, well known by the name of *urinous smell*.

Its properties.

1. Urine reddens paper stained with turnsole and with the juice of radishes, and therefore contains an acid. This acid has been generally considered as the phosphoric; but Thenard has shown that it is in reality the acetic.

2. If a solution of ammonia be poured into fresh urine, a white powder precipitates, which has the properties of phosphate of lime.

3. If the phosphate of lime precipitated from urine be examined, a little magnesia will be found mixed with it. Fourcroy and Vauquelin have ascertained, that this is owing to a little phosphate of magnesia which urine contains, and which is decomposed by the alkali of lime employed to precipitate the phosphate of lime.

4. Proust informs us, that carbonic acid exists in urine, and that its separation occasions the froth which appears during the evaporation of urine.

5. Proust has observed, that urine kept in new casks deposites small crystals, which effloresce in the air and fall to powder. These crystals possess the properties of the carbonate of lime.

6. When fresh urine cools, it often lets fall a brick-coloured precipitate, which Scheele first ascertained to be crystals of uric acid. All urine contains this acid, even when no sensible precipitate appears when it cools.

7. During intermitting fevers, and especially during diseases of the liver, a copious sediment of a brick-red colour is deposited from urine. This sediment contains the rosacic acid of Proust.

8. If fresh urine be evaporated to the consistence of a syrup, and muriatic acid be then poured into it, a precipitate appears, which possesses the properties of benzoic acid.

9. When an infusion of tannin is dropt into urine, a white precipitate appears, having the properties of the combination of tannin and albumen or gelatine. Their quantity in healthy urine is very small, often indeed not sensible. Cruickshanks found that the precipitate afforded by tannin in healthy urine amounted to $\frac{1}{140}$th part of the weight of the urine.

10. If urine be evaporated by a slow fire to the consistence of a thick syrup, it assumes a deep brown colour, and exhales a fetid ammoniacal odour. When allowed to cool, it concretes into a mass of crystals, composed of all the component parts of urine. If four times its weight of alcohol be poured into this mass, at intervals, and a slight heat be applied, the greatest part of it is dissolved. The alcohol which has acquired a brown colour, is to be decanted off, and distilled in a retort in a sand heat, till the mixture has boiled for some time, and acquired the consistence of a syrup. By this time the whole of the alcohol has passed off, and the matter, on cooling, crystallizes in quadrangular plates which intersect each other. This substance is *urea*, which composes $\frac{8}{10}$ths of the urine, provided the watery part be excluded. To this substance the taste and smell of urine are owing. It is a substance which characterises urine, and constitutes it what it is, and to which the greater part of the very singular phenomena of urine are to be ascribed.

11. According to Fourcroy and Vauquelin, the colour of urine depends upon the urea: the greater the proportion of urea, the deeper the colour. But Proust has detected a resinous matter in urine similar to the resin of bile; and to this substance he ascribes the colour of urine.

12. If urine be slowly evaporated to the consistence of a syrup, a number of crystals make their appearance on its surface; these possess the properties of the muriate of soda.

13. The saline residuum which remains after the separation of urea from crystallized urine by means of alcohol, has been long known by the names of *fusible salt of urine* and *microcosmic salt*.

When these salts are examined, they are found to have the properties of phosphates. The rhomboidal prisms consist of phosphate of ammonia united to a little phosphate of soda; the rectangular tables, on the contrary, are phosphate of soda, united to a small quantity of phosphate of ammonia. Urine, then, contains phosphate of soda and phosphate of ammonia.

14. When urine is cautiously evaporated, a few cubic crystals are often deposited among the other salts; these crystals have the properties of muriate of ammonia.

15. When urine is boiled in a silver bason, it blackens the bason; and if the quantity of urine be large, small crusts of sulphuret of silver may be detached. Hence we see that urine contains sulphur.

Composition.

Urine, then, contains the following substances:

1. Water.
2. Acetic acid.
3. Phosphate of lime.
4. Phosphate of magnesia.
5. Carbonic acid.
6. Carbonate of lime.
7. Uric acid.
8. Rosacic acid.
9. Benzoic acid.
10. Albumen.
11. Urea.
12. Resin.
13. Muriate of soda.
14. Phosphate of soda.
15. Phosphate of ammonia.
16. Muriate of ammonia.
17. Sulphur.

These are the only substances which are constantly found in healthy urine; but it contains also occasionally other substances. Very often muriate of potash may be distinguished among the crystals which form during its evaporation. The presence of this salt may always be detected by dropping cautiously some tartaric acid into urine. If it contains muriate of potash, there will precipitate a little tartar, which may be easily recognized by its properties.

Urine sometimes also contains sulphate of soda, and even sulphate of lime. The presence of these salts may be ascertained by pouring into urine a solution of muriate of barytes; a copious white precipitate appears, consisting of the barytes combined with phosphoric acid, and with sulphuric acid, if any be present. This precipitate must be treated with a sufficient quantity of muriatic acid. The phosphate of barytes is dissolved, but the sulphate of barytes remains unaltered.

SECT. XXII. *Of Morbid Concretions.*

Morbid concretions.

Hard substances occasionally make their appearance in different parts of the animal body, both in the solids and the cavities destined to contain the fluids. In the first case they are denominated *concretions* or *ossifications*; in the second *calculi*. Their formation is an irregularity in the animal œconomy, and they often produce the most excruciating diseases. They may be divided into five classes; namely, 1. Ossifications; 2. Intestinal concretions; 3. Biliary calculi; 4. Urinary calculi; 5. Gouty calculi.

1. *Ossifications.*

Ossifications.

Under this name may be comprehended all the concretions which make their appearance in the solid parts of the animal body. The following are the most remarkable of these:

1. Small concretions sometimes form in the pineal gland. They consist of phosphate of lime.

2. Small concretions sometimes form in the salivary glands. These likewise consist of phosphate of lime.

3. Pulmonary concretions are occasionally coughed up by consumptive patients. They consist sometimes of phosphate of lime, sometimes of carbonate of lime, and sometimes of a mixture of both.

4. Hepatic concretions are composed of phosphate of lime, and a tough animal membrane.

5. The concretions which sometimes form in the prostate-gland are composed of phosphate of lime.

2. *Intestinal Concretions.*

Intestinal concretions.

Concretions sometimes form in the stomach and intestines chiefly of the inferior animals. Some of these have been celebrated under the name of *bezoars* for their medical virtue. A great many of them have been analyzed, and no fewer than eight species have been ascertained.

The first species consist of concretions composed of superphosphate of lime, the second of phosphate of magnesia, the third of ammonio-phosphate of magnesia; the fourth of the yellow matter of bile; the fifth of a green-coloured resinous matter; the sixth of small fragments of the *boletus igniarius*; the seventh of balls of hair felted together; and the eighth of woody fibre.

3. *Biliary Calculi.*

Biliary calculi.

Hard bodies sometimes form in the gall bladder and gall ducts, and occasion painful diseases. Four kinds of these calculi have been distinguished; the first kind is composed of a matter resembling spermaceti in appearance, soluble in hot alcohol, and crystallizing as the alcohol cools. This matter has been called *adipocire*. The second kind are angular, because a number of them exist in the gall bladder together. They are composed of adipocire, with a thin external crust of yellow matter of bile. The third kind are of a brown colour, and are supposed to be composed of the altered yellow matter of bile. The gall stones of oxen usually are of this kind. The fourth kind does not flame, but gradually waste away at a red heat.

4. *Urinary Calculi.*

Urinary calculi.

It is well known that concretions not unfrequently form in the urinary bladder, and occasion one of the most dismal diseases to which the human species is liable. These bodies have been carefully and repeatedly examined by modern chemists, who have found them to be very various in their composition. No less than nine distinct substances have been found. These being mixed in different proportions, occasion great variation in the composition of the calculi. The following are the substances:

1. Uric acid.
2. Phosphate of lime.
3. Phosphate of magnesia-and-ammonia.
4. Oxalate of lime.
5. Muriate of ammonia.
6. Magnesia.
7. Phosphate of iron.
8. Silica.
9. Urea.

The four first of these constitute by far the most common and abundant ingredients of urinary calculi.

5. *Gouty Concretions.*

Gouty concretions.

It is well known that concretions occasionally make their appearance in joints long subject to the gout. These concretions, from their colour and softness, are usually distinguished by the name of chalk-stones. They are usually small, though they have been observed of the size of an egg. All of them hitherto examined have been found composed of uric acid and soda, so that they consist of the salt called urate of soda.

PART III.

ON CHEMICAL APPARATUS.

Chemical Apparatus.

HAVING in the preceding part of the article given a pretty full outline of the present state of chemical science, it still remains for us to make our readers acquainted with the nature of the apparatus employed by chemists, and with the manner of conducting chemical experiments. We must warn our readers, however, not to be led away by the too common notion, that an expensive chemical apparatus is indispensible for making any progress in chemical investigations. By far the most eminent chemist who has ever appeared, we mean Scheele, conducted his researches, and completed his discoveries, with a very slender apparatus indeed. The same remark applies to Dr Priestley. And Mr Dalton, one of the most ingenious of the chemical philosophers at present in Britain, has conducted all his acute researches, and made all his important discoveries, with an apparatus so slender as to astonish every person who has seen it, and is acquainted with the numerous and important discoveries made by this celebrated philosopher.

That we may give some interest to this part of our subject, which is naturally dry and disagreeable, though of essential importance, we shall suppose ourselves giving directions to a young student, who wishes to make a complete set of experiments on every branch of chemical science. Now there are four distinct departments in chemistry, which require each a peculiar apparatus, and which must therefore be described separately. These are *heat*, *gaseous bodies*, *liquids*, and *solids*.

CHAP. I.

Apparatus for Experimenting on Heat.

Apparatus for experimenting on heat.

1. THE first and most essential instrument for experimenting on heat, is the *thermometer*, an instrument which, by the expansion of a liquid confined in a glass tube, indicates the temperature of any substance to which it is

applied. For an account of the construction of different kinds of thermometers, we refer to the article THERMOMETER.

Fahrenheit's thermometer.

Fahrenheit's thermometer is the one commonly used in this country. The freezing point on it is marked 32°, the point of boiling water is marked 212°, so that in this thermometer the interval between freezing and boiling water is divided into 180 degrees. The practical chemist ought to be provided with a variety of thermometers; some graduated as high as the boiling point of mercury, others as low as the freezing point of that metal. He should be even provided with a spirit of wine thermometer, graduated as low as 100°. If he is engaged in making experiments on the capacity of bodies for heat, he ought to have thermometers so delicate as to point out very minute changes of temperature. Dr Crawford had a thermometer in which every one of the usual degrees was divided into 50 parts, so that he could measure, with tolerable precision, the hundredth part of a degree of Fahrenheit's thermometer. It was with this very delicate instrument that he determined the specific heat of the gaseous bodies.

Leslie's differential thermometer.

The differential thermometer, invented by Mr Leslie, is an instrument of considerable value in ascertaining minute changes in temperature confined to a particular spot, when our object is not to determine the variation of the temperature of the room in which we are, but the peculiar variation in any point, independent of the general variation. It consists of two equal glass balls joined together by a glass tube bent somewhat in the form of a U. The tube is filled with a coloured liquid. If one of the glass balls be placed in a position hotter than that in which the other ball is placed, the air within it expands and presses down the liquid in the end of the tube nearest it. A scale of degrees is attached to this leg of the tube, by which the heat that the ball experiences is indicated. See the thermometer represented in Plate CXLI. Fig. 1.

Plate CXLI. Fig. 1.

Mortimer's pyrometer.

Various thermometers, or *pyrometers* as they have been called, have been contrived to measure high degrees of heat, as the fusing points of the metals, to most of which a common thermometer cannot be applied. One of the first of these was contrived by Dr Cromwell Mortimer. It consisted of a rod of steel or brass, which, by its expansion, moved a lever turning upon an axis, and pointing out the various degrees upon a plate. Though this instrument is not susceptible of much accuracy, yet as Dr Mortimer employed it to determine the fusing point of tin, lead, zinc, and antimony, and as the degrees which he pointed out are still to be found in modern chemical books, though seldom any reference is made to the original experimenter, we shall give a description and figure of his pyrometer in this place. In Figure 2. AB is a round rod of steel or brass, a quarter of an inch thick and three feet one inch long. When the rod is of brass three feet long, the point A must be of steel one inch long, to prevent its wearing away or losing its point, which conical point is made to screw on and off. CD, *cd* are two iron supporters, joined by a flat cross bar at bottom D*d*, two inches long, in the middle of which is a point $\frac{1}{8}$th of an inch high under B, which goes into a hole at the bottom of the rod B, and serves to keep the rod in its place at bottom; as the cross bar * *, having a hole in it through which the rod passes, does in the middle, or about two thirds up the supporters, and the point A goes into a small hole in the under side of the lever, all which keep the upright rod firm and steady in its place. The iron supporters are flat, or parallel to the front of the machine from C to X, and *c* to *x*, where they are twisted half round, so that the lower parts XD, *xd* stand at right angles with the upper parts. This contrivance gives the freer access to the rod for the sand or fluid into which the machine is set to measure its heat, the supporters standing two inches asunder at D*d*; and that the degrees of heat may be compared uniformly in different experiments, the bottom of the rod must always be immersed to the same height in the matter to be examined. On that account there is a mark made quite round the rod, $1\frac{1}{2}$ inch from the bottom B. For the deeper the rod is immersed into any matter, it will be lengthened the more by the same degree of heat. EF is the lever which turns upon the axis G. At F is fastened a string, which, passing twice round the pulley H, has a weight I hanging to the other end of it, of about $\frac{1}{2}$lb. being enough to keep the string always stretched. At the other end E of the lever is hung another weight L, which must be heavy enough, not only to counterbalance the larger arm GF, but press down on the point A with a weight sufficient to keep it steady. MNO is the back part of the plate, like the dial plate of a clock made of brass, the front of it being as in Figure 3. The pulley H turns on an axis C, in Figure 3, which goes through the plate, and on the other side or front of the dial-plate carries a hand or index AB.

Plate CXLI. Fig. 2.

Plate CXLI. Fig. 3.

Iron being a metal very ill adapted for frequent exposure to heat, in consequence of its great incombustibility, Guyton Morveau has lately proposed to substitute a rod of platinum instead of iron. We do not consider it as worth while to give a particular account of his instrument; but the reader who is inquisitive upon the subject, will find it described in the *Annales de Chimie*, vol. xlvi. p. 276.

Wedgewood's pyrometer.

But the most ingenious, and the best and most convenient method hitherto thought of for measuring high degrees of heat, was contrived by Mr Wedgewood, and the apparatus is well known by the name of *Wedgewood's pyrometer*. It consists of small cylindrical pieces of porcelain clay, carefully made of a determinate size, and baked in a low red heat. He employed for the purpose a particular bed of Cornish clay. This clay was first diffused through water, and the liquid passed through fine lawn. The clay was then suffered to subside and to dry. It is mixed with about $\frac{2}{7}$ths of its weight of water, kneaded into a paste, and formed into small pieces, in little moulds of metal, $\frac{6}{10}$ths of an inch in breadth, with the sides pretty exactly parallel; $\frac{4}{10}$ths of an inch in depth, and 1 inch long. These pieces, when perfectly dry, are put into another iron mould or gage, consisting only of a bottom with two sides, half an inch deep, to the dimensions of which sides the breadth of the pieces is to be paired down. The constituents of the clay employed, according to Mr Wedgewood's analysis, are $\frac{2}{5}$ths alumina, and $\frac{3}{5}$ths silica.

It is the property of clay pieces, after having been baked in a red heat, to shrink permanently in their dimensions, according to the degree of heat to which they have been exposed. This diminution of bulk is the principle of Wedgewood's pyrometer. For measuring the diminution which these pieces undergo when exposed to heat, a gage is made of two pieces of brass, 24 inches long, with the sides exactly straight, divided into inches and tenths, fixed half an inch asunder at one end, and $\frac{3}{10}$ths at the other, on a brass plate; so that one of the clay pieces, when pared down in the iron gage, will just fit the wide end. This gage is divided into 240 degrees, each of which, of course, is one tenth of an inch distant from the succeeding one. The wide extremity of the gage is marked 0, and the degree at the narrow extremity is marked 240°. Let us suppose a clay piece to

Chemical Apparatus.

be exposed for a few minutes to the heat of a furnace, and to have been diminished in bulk by the heat one-fifth part. It is obvious, that when applied to the gage, it will slide up just one half of the whole, and will stop over against the degree marked 120°, indicating the heat of the furnace to have been 120°.

Wedgewood, by a very ingenious set of experiments, contrived to connect his pyrometer scale with that of Fahrenheit. He found that 0, on his scale, corresponded to $1077\frac{1}{2}$° of Fahrenheit, and that every degree of his pyrometer is equal to 130° of Fahrenheit. Hence, 240° Wedgewood, or the extremity of the scale, corresponds with 32277° of Fahrenheit. For the description of his pyrometer, and the experimental investigations by Wedgewood himself, the reader is referred to the *Philosophical Transactions*, 1782, vol. lxxii. p. 305; and 1784, vol. lxxiv. p. 358. Objections have been made to the accuracy of Wedgewood's pyrometer, from various quarters; but none of the objections which we have seen are warranted by accurate experiments.

2. Some very accurate instruments for ascertaining the expansion of solid bodies by heat, have been invented by Ellicott, Smeaton, and Ramsden. For an account of these, we refer the reader to the *Philosophical Transactions*, 1736, vol. xxxix. p. 297; and 1751, vol. xlvii. p. 479; and 1754, vol. xlviii. p. 598.

3. For containing freezing mixtures, it is best to employ a double vessel of tin-plate, which, in consequence of the confined stratum of air, prevents the external atmosphere from acting so speedily on the mixture, and destroying its efficacy. Several convenient enough vessels for such purposes have been figured and described by Mr Walker, in the *Philosophical Transactions* for 1795, vol. lxxxv. p. 270.

4. For ascertaining the specific heat of bodies, or the capacity of bodies for heat, a very simple method was employed by Meyer. And from the subsequent experiments of Leslie and Dalton, there is reason to believe that the method is accurate. He took equal bulks of the bodies whose specific heats he wanted to know, heated each to a given temperature, and then allowed them to cool a given number of degrees. The time of cooling in seconds multiplied into the specific gravity of each body gave its specific heat. When liquids are the subjects of experiment, they must of course be confined in a vessel. The specific heat of this vessel must be previously determined, and the effect which it has upon the rate of cooling of the liquid must be attended to, otherwise the results obtained will be inaccurate.

The apparatus employed to ascertain the specific heat of bodies by mixture, by Black, Wilke, Crawford, &c. requires no description. But there are two pieces of apparatus connected with this subject, of so complicated a nature, that they will require to be particularly noticed. The first of these is the apparatus contrived by Crawford, for determining the specific heat of gaseous bodies: The second is the instrument invented by Lavoisier and La Place, for ascertaining the specific heat of bodies, by the quantity of ice which they are capable of melting. To this instrument they gave the name of *calorimeter*.

Plate CXLI. Fig. 4.

Crawford's apparatus for determining the specific heat of the gases.

Dr Crawford's very delicate apparatus for determining the specific heat of the gases, was the following: AB, CD, Fig. 4. represent two slight brass cylindrical vessels, of equal weights and capacities; the weight of each was 7 ounces, 3 drachms, and 38 grains, troy; the length, $8\frac{7}{8}$ inches; the breadth, $2\frac{1}{4}$ inches near the upper extremity, and $2\frac{1}{8}$ inches near the bottom. They were each capable of containing 20 ounces troy of water; and, consequently, the solid contents of each is 37.91 cubic inches. These cylinders terminate in the small tubes *ls*, *rk*, at the extremities of which are fixed the brass cocks *s* and *k*. These cocks are joined to the cross bar MN, which consists of two elastic brass plates that are screwed together at the middle, but are capable of being separated from each other to a little distance at their extremities; in consequence of which, the necks of the cocks that are fixed to the stems of the brass vessels, can be slipped in between them, where they are lodged in grooves formed for receiving them, and are made fast by small screws that pass through the extremities of the plates. To the middle of the cross bar is fixed a square socket, the inner surface of which is finely polished, and which is of such a size as to be accurately adapted to the polished upright bar EF, and at the same time easily moveable upon it. At equal distances from the upright bar, are placed the tinned vessels, GH, IK, that have a little more than double the capacity of the brass cylinders. The distance of these vessels from the upright bar are so adjusted, that when the cylinders are made to descend, they shall be directed by the bar and socket precisely into the centres of the tinned vessels; and when, in descending, they have arrived at one-eighth of an inch from the bottoms of those vessels, they are stopped by means of a pin fixed in the upright bar at the point *d*. The cylinders being made for the purpose of receiving the gases whose specific heats were to be ascertained, were made as slight as was consistent with standing the external pressure of the atmosphere when exhausted. With a view to diminish the inaccuracy unavoidably occasioned by the heats communicated by the cocks *s* and *k*, and by the cross bar MN, the tubes *ls*, *rk*, were made very slight, and of a considerable length; the distance from the cocks to the brass cylinders being $4\frac{7}{8}$ inches. From the length and slightness of the tubes, it was found that the brass cylinders could not be kept sufficiently steady in the centres of the tinned vessels by the cross bar MN. For this reason, another bar, OP, was added, a lateral view of which is given in Fig. 5. In this figure, *ab* represents a narrow brass plate, of a considerable thickness, to which is fixed the socket *op*, moveable upon the upright bar formerly described. The two thin plates *cn*, *dk*, are riveted to *ab*, at the points *o* and *p*; and their extremities, *l* and *m*, are formed into grooves, which are adapted to one half of the circumference of the stems of the brass cylinders, to the other half of which are closely applied two brass pieces, which are also grooved, and which are fastened to the plates by the screws *r* and *s*. The two male screws, *g* and *h*, are passed through the extremities of the thick plate *ab*. These are introduced into two corresponding female screws, in the thin plates *cn*, *dk*, by means of which it is evident, that the latter may be made to approach nearer to the former, or to recede to a greater distance from it. This motion is communicated to the stems of the brass cylinders, by means of which they are adjusted in such a manner, as that when they are introduced into the water, they shall be accurately in the centres of the tinned vessels, where they are kept steadily in their proper positions. The superior and inferior cross bars are connected together by a thin plate of brass,

Fig. 5.

which passes from the socket of the former to that of the latter, and which is made fast by means of screws. The screw that fixes this plate to the socket of the inferior bar, is of such a length, as when screwed home, to extend to a small distance beyond its inner surface, by which means the apparatus, in descending along the upright bar, may be fastened to any part of it.

Plate CXLI. Fig. 4.

To each of the tinned vessels (see Fig. 4.) two very small mercurial thermometers are fixed, which are of different lengths; the larger reaching as far as the centre of the vessel; the shorter extending a little lower than the surface. The thermometers *a b* and *c d*, which indicate the heat in the vessel GH, are applied to a thin plate of ivory *e f*, which has two scales divided upon it, one for each thermometer. This plate is fixed to the vessel by means of a clamp *g h*, the shank of which consists of two thin elastic brass plates, united at the top, and separable from each other at the lower extremity. For the purpose of admitting the thermometers, the projecting part *o v*, having the figure of a parallelopiped, was added to the tinned vessel. The exterior side of this projection is received between the plates of the shanks described above. These plates are closely applied to it, by means of their elasticity, in consequence of which the clamp is steadily retained in its position, at the same time that it admits of a considerable degree of elevation or depression. Hence the depth to which the thermometers are sunk may be varied at pleasure; and, in order that this depth may be accurately known, a scale of equal parts is divided upon the exterior plate of the shank. Through the upper part of the shank is passed a small male screw S, similar to that which is used in adjusting the focus of a telescope. This is introduced into a corresponding female screw, inserted in the ivory plate, which has the thermometers fixed to it; and as that plate is suspended in the clamp by a pin, around which it has a free motion, it is manifest, that, by turning the above mentioned screw, the thermometers may be made to approach nearer the centre of the vessel, or to recede farther from it.

The two brass cylinders in this instrument were intended to hold the gases experimented upon. The gas to be used was first introduced into a tin syringe, previously filled with water. To the end of this syringe was fixed a worm, terminating in a flaccid bladder. The worm was surrounded by a mixture of salt and ice. The gas was slowly forced through this worm from the syringe, and extended the flaccid bladder. The object of this was to free the gas as much as possible from moisture, by exposing it to the cold of the freezing mixture. The brass cylinders being previously exhausted by means of an air pump, the bladder was screwed to the top of the stem, and the stop-cocks being opened, the gas rushed in and filled the cylinder.

Fig. 6.

The next object was to heat the cylinder containing the gases equally, and without moistening them. Dr Crawford's contrivance for that was the following: AB (Fig. 6.) represents a quadrangular tinned vessel, that has the two smaller vessels, CD, EF, fixed to its bottom by means of dovetails, along which they may be made to slide, and may be so adjusted, that their distances from each other shall be equal to the distances of the cylindrical vessels in which the air is contained; their size being such, that they shall be nearly accurately filled by those vessels, when the latter are introduced into them. It is therefore manifest, that warm water contained in the large vessel AB, and coming into contact with the external surfaces of the smaller vessels CD, EF, will necessarily communicate a part of its heat to those vessels, and to the cylinders which are placed in them. If the cylinders had been heated by being immediately immersed in warm water, a quantity of moisture would have adhered to their sides, which would have produced an inaccuracy in the experiment. Two small thermometers, *l*, *r*, are introduced into the brass cylinders (Fig. 4.), in order to indicate the heat which the gas contained in them requires. Each of the brass cylinders is enveloped in flannel, in order to confine the heat as much as possible.

Plate CXLI. Fig. 4.

Such is the ingenious apparatus of Dr Crawford. It remains to say a few words upon the way in which his experiments were conducted. Suppose he wanted to determine the relative specific heats of common air and oxygen gas, he filled one of the cylinders with common air, and the other with oxygen gas. The cylinders were both heated equally by the contrivance exhibited in Fig. 6. They were then suddenly let down into the tinned vessels, IK, GH, (Fig. 4.) containing each an equal quantity of water of the same temperature. They were allowed to remain for about 15 minutes, and being withdrawn, the water in the tinned vessels was agitated for a little, and its temperature taken. As the weight and temperature of each brass cylinder and its flannel covering was the same, if there was any difference in the temperatures of the water in the two tinned vessels, that difference must have been owing to the heat communicated by the gas in the one cylinder being greater than the heat communicated by the gas in the other cylinder. Suppose, for example, that the water exposed to the action of the cylinder containing the oxygen gas, were one degree hotter than the water exposed to the action of the cylinder containing the common air; it follows from this, that 37.91 cubic inches of oxygen gas, when they cool a certain number of degrees, give 1° more heat to a certain weight of water, than the same bulk of common air. From the knowledge of this fact, the capacity of each for heat is easily inferred. Such was the ingenious method employed by Dr Crawford; and the care and address with which his experiments were conducted cannot be too highly praised. At the same time, we are afraid that his results are not near approximations to the truth; and that the unavoidable errors of experiment, when the whole difference between the temperatures amounts only to one or two tenths of a degree, are such, as to render every result obtained by his method of little value. Though the time which a body takes in cooling, when placed in the different gases, does not depend upon their capacity for heat alone, yet as that capacity influences the result, valuable inferences may be drawn from experiments made in that way; and they promise to lead ultimately to a much more precise knowledge of the capacity of the different gases for heat, than any other method which has been hitherto thought of.

Calorimeter.

The *calorimeter* is an instrument contrived by Lavoisier and La Place, for determining the specific heat of bodies, and was first described by them in the Memoirs of the French Academy for 1780, p. 355. Lavoisier afterwards re-published the account of it in his Elements of Chemistry, Part III. Chap. iii. It was founded upon this well known fact, that if a hot body be surrounded by a sphere of ice, none of the heat can penetrate through the ice, but will be all employed to melt it. Hence the quantity of ice melted ought to measure the quantity of heat which has escaped out of the hot body, and, of course, gives us the relative specific heats of all the bodies examined in this manner. The calorimeter is represented in Fig. 7. It consists of three vessels enclosed within each other. The innermost of these, *ffff*, into which the substance submitted to experiment is put, is composed of a grating, or cage of iron wire, supported by several iron-bars. Its opening, or mouth, is covered by a lid, which is composed of the same materials. The middle cavity, *bbbb*, is intended to contain the ice which surrounds the interior cavity, and which is intended to be melted by the heat of the substances employed in the experiment. The ice supported by the grate, *mm*, at the bottom of the cavity, has under it a sieve. In proportion as the ice contained in the middle cavity is melted by the heat disengaged from the body placed in the interior cavity, the water runs through the grate and sieve, and falls through a conical funnel into a receiver placed below it. The external cavity, *aaaa*, is filled with ice, to prevent any effect upon the ice in the middle cavity from the heat of the surrounding air; and the water produced from it is carried off by the pipe ST, which shuts by means of the stopcock *r*. The whole machine is covered with a lid, made of tin-plate and painted.

Plate CXLI. Fig. 7.

When this machine is to be used, the outer and middle divisions are filled with pounded ice, well rammed, and without any vacuity. The machine is then opened, and the substance, submitted to experiment, being placed in the interior cavity, it is instantly closed. After waiting till the body is cooled down to the freezing point, the water which has run out from the middle cavity is carefully weighed. This water obviously measures the quantity of heat which has escaped from the body experimented upon, during its cooling to the freezing point. For the various precautions employed by the French philosophers, during their experiments with this apparatus, to ensure accuracy, the reader may consult Mr Lavoisier's account of them in his Elements of Chemistry, to which we have referred above. The only person in this country, who has attempted to repeat the experiments of Lavoisier and La Place, was the late Mr Wedgewood. In his trials a phenomenon took place, which prevented him from being able to draw any conclusions from his trials. The water which ran from the melted ice actually froze again, though the temperature of the ice was at 32°. Such a phenomenon, unless it can be obviated, obviously makes the calorimeter, ingenious as the contrivance at first sight appears, entirely useless as an instrument for investigating the specific heat of bodies. The freezing of the water seems to be owing to the cold produced by its evaporation. From Mr Wilson's experiments, it appears that the evaporation of ice is greatest, when its heat is 32°. Now, as the temperature of the water, produced by the melting of the ice in the calorimeter, cannot much exceed 32°, it is obvious that a very slight diminution of temperature by evaporation will be sufficient to begin congelation; and when congelation once begins, the attraction of the spiculæ of ice formed for the particles of water, will probably tend to increase the quantity of ice.

There are no other apparatus connected with heat, which seem to require particular description. The contrivances of Mr Leslie and of Count Rumford possess great ingenuity; but are so simple, that the reader can find no difficulty in understanding them.

Chap. II.

Apparatus for Experiments with Gases.

Apparatus for experiments with gases.

This branch of Chemistry requires by far the most expensive and complicated apparatus. We shall satisfy ourselves with describing the most important requisites. Almost every chemical experimenter has added something of his own to this department of chemical vessels. Hence it would be an endless and a useless task to describe every thing that has been proposed, or even brought into use.

Water troughs.

1. The first requisite is a water-trough, for preparing the gases, and for containing the vessels in which the gases are confined. These are of various sizes, according to the extent of the laboratory, or the objects which the proprietor has chiefly in view: the largest are made of wood and lined with lead, about four feet long, three wide, and two deep. They have a wooden shelf fixed about three inches under the surface, upon one side of the trough, for holding the glass jars. This shelf is perforated with holes, for the conveniency of pouring the gases from one jar to another; and these holes are usually funnel-shaped, having their wide mouth at the under side of the shelf. This trough, when to be used, is to be filled with clean water. Water-troughs are often made much smaller than this. In that case, they are only made of tin-plate and japanned; or what would be much better, and perhaps even ultimately cheaper, would be to make them of copper, which ought likewise to be japanned. A trough of this kind, two feet long, sixteen inches wide, and as much in depth, with a shelf soldered to one of its ends, also of copper, and placed about two inches under the surface, would answer a great variety of purposes, and, from its small size, would be convenient, as it could easily be carried from one place to another, even when full of water. We shall give a figure of the small tinned iron water-troughs that are commonly used in London. *a* (Fig. 8.) is a deep oblong trough, made of thin tinned iron, well japanned, generally 18 inches long, 9 broad, and 14 deep. About 3½ inches from the top is a shelf of the same material, extending entirely across the trough, and rather more than a third of its length. This shelf is given inverted in Fig. 9. to show an oval rim projecting from it in the centre, of which are two small holes, the use of which is to secure and convey the gas into any vessel set upon it, (as the bottle Fig. 8.) This shelf has also two larger holes to receive two bottle supporters. Fig. 10. and *b*, Fig. 8.

Plate CXLI. Fig. 8.

Fig. 9.

Fig. 10.

2. To prepare the gases, various vessels may be employed, according to the nature of the gas wanted. Small retorts, with long beaks, (see Fig. 11. and 12.) answer very well; or flasks, with bent tubes ground into them. (See Fig. 13, 14, and 15.)

Fig. 11, 12, 13, 14, 15.

3. To receive the gases as they come over, the most simple apparatus consists of glass phials, with ground stoppers, made perfectly air tight. These may be filled one after another, and, the stoppers being fitted in, may be placed with their mouths inverted in a vessel of water, and kept till wanted; or glass jars may be employ-

ed, open below and shut above, as those represented in Fig. 16 17. Plate CXLI.; and in Fig. 1. Plate CXLII.

Plate CXLI. Fig. 16, 17.

Gazometers.

4. When the quantity of gas prepared is considerable, it is necessary to be provided with larger vessels than any of those already mentioned to contain it. Such vessels are usually made of tin-plate japanned, or partly of tin-plate, partly of glass, and they are known by the name of *gazometers, gas holders*, air holders. Their construction is very various, according to the fancy of the chemist, or the object which he has in view. We shall give a description of some of the most useful.

Plate CXLII. Fig. 3, 4.

Fig. 3. and 4. represent the outline of a very convenient vessel for holding oxygen gas. It is made of tin-plate, well japanned, both withinside and without. It may be of any size: the vessel, of which this is a representation, held about 2000 cubic inches. It is a cylindrical vessel, close on all sides, and ought to be pretty strong to resist the pressure of the atmosphere, which tends to force out gas, or to force in air according to the changes in its density which take place. It is furnished with three mouths, A, B, C. The first at the top, the second at the side as high up as possible, the third at the bottom. A and B are each provided with a stop-cock. The stop-cock A is soldered into the tube D, which goes to the very bottom of the vessel to which it is soldered, in order to increase the strength of the air-holder. The tube D, towards its bottom, is perforated with a number of holes. To the extremity of the stop-cock B, the piece of bent tube E is ground, so as to be air-tight, but to move freely round the extremity of B, which is turned up to receive it. And to the extremity of E, the long tube F is likewise ground, so as to be air-tight, yet capable of moving freely. These two tubes, by their motion, form an universal joint, so as to enable the operator to turn the extremity of the tube F any way he thinks proper. The mouth C consists of a tube about an inch in diameter, introduced into the vessel, near the bottom, at an angle of about 45°. It is provided with a stopper, which screws into it and shuts it close. G is a glass tube, fixed into the top and bottom of the air-holder, and graduated. The use of it is to shew the operator how much gas the vessel contains. It is a large glass conical vessel, made to fit into the upper end of the stop-cock A.

A few words will explain the method of using this vessel. The first step is to fill it with water. For this, the mouth C must be shut, and the stop-cocks A and B opened. Water is then poured into the glass vessel H, which, running down the tube D, makes its escape through the holes in its bottom, and fills the vessel, while the common air makes its escape by the stop cock B. When the air-holder is quite full of water, the stop-cocks A and B are to be shut, the glass vessel H removed, and the stopper of the mouth C removed. As the vessel is completely air tight, the water cannot make its escape by the mouth C, because the angle at which it enters the vessel, prevents any common air from entering. The mouth of the tube connected with the apparatus for furnishing oxygen gas being introduced into C, the gas rises gradually to the top of the air-holder, and the water runs out by the mouth C. When the process is finished, the mouth C is to be shut; and if the vessel be a good one, the gas may be kept in it for many months without undergoing much alteration. Suppose we want a portion of the oxygen gas out of this air-holder, for any particular purpose, we have only to introduce the point of the tube F into the mouth of the vessel which we mean to contain the oxygen gas, and then to pour a quantity of water into the glass vessel H, which must be replaced for the purpose. The stop-cocks A and B being opened, the water runs down the tube D, and forces the oxygen gas to escape through the tube F. By this method any quantity of the gas wanted may be easily procured.

Plate CXLII. Fig. 3, 4.

Another gazometer, of a different construction, is represented in Fig. 3, 4. which are merely different views of the same vessel, and the same letters in both refer to the same parts. Like the former, it is made of tin-plate, well japanned, both within and without. *aa* is the outer pail, or circular vessel, with a spout at top. Two tubes, *d* and *e*, (each filled with a stop-cock externally), are firmly soldered to the sides of the pail: the tube *d* penetrates at the bottom of the pail, and proceeds to the centre, where it joins the termination of the tube *e*, which enters the top of the pail, and proceeds downwards; and from the place of junction, the upright tube *g* rises through the middle of the pail, a little above the level of its upper rim. The vessel *b* is a cylinder, open only at bottom, and of less diameter than the pail into which it is inverted, and can move up and down freely. This cylinder has a solid stem, *c*, which passes through a hole in the wooden cross bar of the frame, round the top of the pail, and serves both to keep the cylinder in a perpendicular direction when moving up and down, and to indicate the quantity of inclosed gas by the graduation on its surface. The weight of the cylinder is counterpoised by weights put into a scale dish, which is connected with the top of the cylinder by a cord and pulley. The pail has besides an opening through its bottom, closed by a separate stop-cock, *f*, by which the water may be drawn off. The whole apparatus is conveniently supported on a heavy wooden stool. To use this gasholder, first let the cylinder fall to the bottom of the pail, and pour water into the spout of the latter till it is quite full; then shut the cock *e*, and open *d*, and connect with it the tube which conveys the gas immediately from the retort or other vessel in which it is produced: or, if more convenient, shut *d*, and convey the gas through *e*. The gas rises through the upright tube *g*, to the top of the cylinder *b*, which it gradually lifts up; and care must be taken to keep in the scale-dish sufficient weight to allow the cylinder to move with perfect freedom. When all the gas wanted is obtained, shut the stop-cock, and it remains in the air-holder till wanted. To take out any of it, connect with either of the stop-cocks a bent tube, and insert the mouth of it into a vessel destined to receive the gas, remove the weights out of the scale-dish, and open the stop-cock. The weight of the cylinder *b* will press out the gas and fill the vessel.

As the weight of the cylinder is constantly increasing during the whole of its rise out of the water, it is necessary to be continually adding weights to the scale-dish to compensate for this increase, otherwise the gas will be more and more compressed, and at last will cease to enter altogether. Or this increase may be still better compensated, by making the cord pass over a spiral pulley, by means of which, the weight in the scale-dish will act more and more powerfully as the cylinder rises, and thus compensate the increase of its weight.

Many other gas holders have been contrived by chemists; but it is needless to describe them, as they may be essentially referred either to one or other of the two which we have figured.

5. Many gases are absorbed with such avidity by water, that it is necessary to prepare them over mercury. Hence a mercurial trough is also requisite for all those who wish to investigate the properties of gaseous bodies with any thing like success. Mercurial troughs are very various in their shapes. One of the most usual and best shapes is represented in Fig. 5. It may be made of mahogany, or it may be cut out in marble; or what is now most common, it may be of iron, and covered externally with wood. *a* is the cistern filled with mercury, in which the glass jars are to be filled, and then slid upon the shelf visible in the Figure. The glass jars used with this trough must be smaller than those used for the water trough, and they ought to be stout. As they are liable to be overturned by the weight of the mercury, care must be taken to fix them.

Mercurial troughs.

Plate CXLII. Fig. 5.

Mercurial gas-holders are used, made on a similar plan with the second kind of gas-holders described above. The outer case is cast iron. There is an inner cylinder of cast-iron, at a little distance within the interval between them, filled with mercury; *v*, a glass jar, is made to move freely between both, and to receive the gas. The reader will easily conceive a gas-holder of this kind without a figure.

Method of measuring the bulk of gases.

6. It is necessary to be in possession of a method of measuring the bulk of our gases with accuracy. For this purpose, the jars into which they are received should be accurately graduated. The best graduation is into cubic inches, and their decimal parts. The experimenter should perform this graduation himself, otherwise he can very seldom depend upon its accuracy. He should first provide himself with some glass tubes, shut at one end and open at the other, and of as equal a bore as possible. Some of them should be $\frac{1}{4}$th inch in width, others $\frac{1}{8}$th, and some may be as wide as $\frac{5}{8}$ths, or even $\frac{3}{4}$ths of an inch. A long ribbon of white paper, about $\frac{1}{5}$th inch wide, should be pasted along the whole length of the tube by means of gum water. That it may adhere to the glass in every part, a quantity of twine may be wrapt round it while wet, and the tube may be set aside till next day, when the paper will be found adhering to it closely in every part. The tube is now set in an exact perpendicular direction with its open mouth uppermost. We shall suppose it our intention to graduate this tube into hundred parts of a cubic inch. The best method of doing this is the following:

Provide a quantity of mercury, and ascertain its specific gravity with accuracy. This being known, it is easy to ascertain the weight of $\frac{1}{100}$th cubic inch of mercury. For example, the mercury which we are in the habit of using is of such specific gravity, that $\frac{1}{100}$ of a cubic inch weighs 34.46 grains. Weigh out this quantity of mercury, and introduce it into a tube terminating in a point, and of a bore as narrow as possible, but still allowing the mercury to run out freely. The mercury should occupy about 3 inches in length of it from the pointed end. Mark carefully with a file the part of the tube to which the mercury rises. This tube, thus prepared with a pair of good scales, will enable you to graduate your tube with considerable rapidity. Pour the first $\frac{1}{100}$ cubic inch of mercury into your tube, observe its surface, and draw a fine line with a pencil upon the ribbon of paper over against this surface. Draw up into your pointed tube, by means of the mouth, a quantity of mercury, till it just rises to the mark. Put this quantity into your scales, and, if you manage matters with tolerable dexterity, you will find that it will weigh exactly 34.46 grains. Pour this into your tube, and draw a pencil line over against its surface. Proceed in this way till you have filled your tube to the top. By this method, you have got your tube graduated upon the ribbon of paper. To graduate it upon the tube itself, which is requisite, procure some small triangular files, and moistening one of the angles, draw it along the pencil marks upon the paper. You soon cut through the paper, and make an impression upon the glass tube; and, if you manage matters with address, you do not injure the adhesion of the rest of the paper to the tube. At every 5th degree, make the line upon the tube somewhat longer than the preceding 4 lines; and make the line still longer at every 10th degree. Having thus marked the degrees upon the whole length of the tube, dip it into water, and wash off the paper. If you have used the file properly, you will now find the lines engraven upon the tube very neatly and distinctly. You now with a diamond write the numbers 10, 20, 30, &c. opposite to the respective lines upon the tube.

Large jars are to be graduated in the same manner, only you divide them into cubic inches instead of $\frac{1}{100}$th of cubic inches. It is necessary also to use water instead of mercury. As a portion of the water adheres to the vessel in which you weigh it, you must make an allowance for this quantity, otherwise your marks will represent something less than cubic inches. This error, though small, becomes extremely sensible after being repeated one, two, or three hundred times.

7. Suppose it required to take a small quantity of gas out of a jar standing over water, and introduce it into a vessel standing on the mercurial trough, without taking any of the water along with it, or even wetting the inside of the vessel. This may be done by a very simple instrument, first contrived by Mr Cavendish, and represented in Fig. 6. It consists of a glass tube, graduated into $\frac{1}{100}$ths of a cubic inch, open at both ends: One end, however, drawn out to a capillary tube. This tube being first filled with mercury, is to be introduced into the jar standing on the water trough, with the finger shutting up closely the end A, which must be undermost. When fairly within the jar, you withdraw the finger a little from one side of A, and let the mercury run out, till its upper extremity comes opposite to the degree, marking the quantity of gas which you want to take out. The finger immediately resumes its place. By this contrivance, the gas is made to enter at the capillary end B, and to fill what part of the tube you have a mind. You then withdraw the tube from the water trough, holding your finger in its position all the while, and wipe the outside of the tube dry with a cloth. You then carry it to the mercurial trough, place the point B under the jar or tube into which you wish to introduce the gas, and bending the tube so, that the whole of A is under the surface of the mercury, and the end A somewhat lower than the end B; remove your finger from A, the mercury runs in, and the gas makes its escape from the capillary end B, and enters into the vessel prepared for its reception.

Plate CXLII. Fig. 6.

Method of measuring the specific gravities of gases.

8. The next object after being able to measure the bulk of gases, is to ascertain their specific gravity. To do this, it is necessary to be provided with a good air pump, or at least with an exhausting syringe. Very ex-

tensive apparatus were contrived by Lavoisier and others for weighing gases; but they are unnecessary, and do not even answer so well as a much more simple and cheap contrivance which we shall now explain. Let a Florence flask, or one of those thin glass flasks that come to this country from Italy filled with oil, be well cleaned, and fitted with a cap and brass stop cock, both as light as possible. This flask, by means of an intermediate short brass tube properly furnished with screws, is made to fit to a jar standing over water, and furnished with a stop cock at the upper end, and to another jar of the same construction standing in the mercurial trough. Suppose we want to take the specific gravity of a gas standing over water. We first weigh the flask and stop-cock with as much accuracy as possible. We then exhaust it of air and weigh it again, noting the loss of weight, which indicates the quantity of air drawn out of the flask. Let us suppose this loss of weight to amount to 10 grains. We now screw the flask to the jar containing the gas to be weighed, and turning the stop-cocks, the gas rushes in and fills the flask. We must take care that no water or mercury make its way into the flask along with the gas. This is best guarded against, by filling the intermediate brass tube with cotton. We now weigh the flask a third time. If its weight be the same as at first, then the gas is of the same specific gravity as common air; if it is lighter, the gas is lighter than common air; if it is heavier, the gas is heavier than common air. Suppose, for example, that the flask wants 5 grains of its original weight. We infer, that the weight of air is to the weight of our gas as 10 to 5, or that its specific gravity is one half of that of common air. By this easy method we determine the specific gravity of any gas, taking the specific gravity of air at 1.00; and knowing that at the temperature of 60, and when the barometer stands at 30 inches, 100 cubic inches of air weigh 30.5 grains, we can easily deduce from our experiments the absolute weight of our gas. No correction is necessary, either for temperature or for the height of the barometer, because all gases undergo the same change in bulk by heat and pressure.

Balance for specific gravities.

9. One essential requisite for taking the specific gravity of gases, is a good balance. The one which we employ was made by Mr Cuthbertson of Glasgow, and weighs easily to the hundredth part of a grain, so that we are sure of our specific gravities of gases to two decimal places, but no farther. As Mr Cuthbertson's beams differ in several particulars from any others that we have seen, we shall give a figure and short description of one of them, and mention some of its excellencies and defects. See Fig. 7.

Plate CXLII. Fig. 7.

The beam *ab* is made of cast steel; and, as will be seen by the Figure, is very slender, though of considerable length. To prevent it from warping or bending, the two slender wires *c*, *c* are riveted into the ends of the beam, and screwed tight to the upper end of the tongue of the balance. These wires, or *stays*, constitute the chief difference between this and other balances. There is nothing peculiar in the construction of the other parts. The sensibility is owing chiefly to the great length of the beam. The principal defect of this balance, is the way in which it is suspended to the top of the glass case by means of the hollow brass cylinder *d*. A solid cylinder of brass, attached to the top of the balance, plays in this hollow cylinder; and by means of the string *e*, and weight *f*, the balance is raised above the stand, or let down to it at pleasure. This mode of suspension gives such a tendency of shaking to the balance, that the process of weighing is very tedious.

Electrical machine.

10. Many of the gases are of an inflammable nature, and it is by their combustion with oxygen that the inferences are drawn with respect to their nature and constituents. The combustion of the gases requires a peculiar apparatus, which it will be requisite to describe. A good electrical machine is the first requisite. This may be either a plate machine, according to the more modern and fashionable construction, or a cylindrical one. All that is wanted is, that it should give out strong sparks when in proper order; for burning the gases, a very strong glass tube is used, about four inches long, and $\frac{3}{4}$ths inch wide, shut at one end, and open at the other. This tube is graduated, and should hold about three cubic inches. Two holes are drilled in it opposite to each other near the top, and into these are cemented two brass pins, which project into the tube, and approach near enough to transmit a spark from one to the other externally. These pins terminate in small rings. The mixture of gases being put into this tube, it is firmly fixed down in a water or mercurial trough by a strong iron screw. The brass pins being now connected with the electrical machine, a spark is made to pass from the one to the other, which sets the gas on fire.

When this experiment is made over mercury, the sudden expansion produced by the combustion of the gas, is apt to drive some of the mercury out of the trough. To remedy this inconvenience, the French chemists usually put a stop-cock at the bottom of their detonating tube, which they shut before passing the electric spark. But this is a bad method, as the shock is very apt to break the glass tube however strong, unless the quantity of gas burnt be very small. Mr Pepys has contrived the apparatus represented in Fig. 8, which answers very well. The detonating tube *a* is supported by a strong iron stand *c*, which has a strong spring near the foot, which draws out after the manner of a steelyard when the concussion is given. The inconvenience may be remedied also, by placing the detonating tube in a copper cylindrical vessel about 3 inches deep, and filled with mercury. The depth of the mercury prevents the concussion from being so violent, as to drive out and spill the mercury.

Plate CXLII. Fig. 8.

Henry's apparatus for the slow combustion of gases. Fig. 9.

11. It may be worth while to describe here an apparatus contrived by Dr Henry, for the slow combustion of inflammable gases. This apparatus is represented in Fig. 9. *aaa* is a pneumatic trough filled with water. *nn* a large glass jar likewise containing water. *cc* is a stand, to which the graduated air holder *b* is made fast, by means of the moveable arm *dd*. *oo* is another air-holder, fixed by the plugs *vv* into the glass jar *nn*. It is furnished with the stop cocks *q*, *r*, and the bent tube *s*, which passes into the water cistern, and passes up a certain way into the air-holder *b*, terminating in the iron burner *t*. The air-holder *b* is closed at top by a brass cap *e*, and stop-cock *f*, the lower orifice of which is tapped internally, for the purpose of receiving a small screw at the end of the copper wire *g*. The gas to be burnt is put into the air-holder *oo*, while the air-holder *b* is filled with oxygen gas. By opening the stop cocks *q*, *r*, and letting water run into the jar *nn*, the gas is gradually forced through the tube *ss* into the air-holder *b*. An electric spark sets it on fire at *t*, and it continues to burn till the oxygen or the inflammable gas

are wasted. The rapidity of the flow of water is regulated by the cocks *x*, *x*. The water makes its way into the air-holder by the holes *w*, *w*, drilled in the plate to which its bottom is ground. *u* is a wire to conduct the electricity; and *h* is the wire which conducts the electricity from the receiver *i*.

Retorts.

12. In many experiments, retorts or flasks furnished with stop-cocks are requisite. They are first exhausted by means of an air pump, and then filled with the gas to be experimented upon. Thus all contact of water may be prevented, and the gases may be previously dried at pleasure.

13. The various tubes used by chemists under the name of eudiometers, do not seem to require a particular description.

CHAP. III.

Apparatus for Experiments on Liquids.

Apparatus for experiments on liquids.

Plate CXLII. Fig. 10.

Plate CXLIII. Figs. 1, 2, 3, 4.

Fig. 5.

SEVERAL of the vessels employed in experiments on liquids, as retorts and flasks, have been already mentioned. We shall take notice of a variety of other vessels. They are in general so simple, that they will be easily understood without much explanation. Fig. 10. represents a balloon glass receiver; and Fig. 1. a matrass, with a wire twisted round its neck to hold it by when hot. Fig. 2. is a glass funnel. Fig. 3. a precipitating vessel. Fig. 4. represents a copper still fitted into a furnace, with the worm and refrigetory. *a* is the still, *b* the head, *c* the worm passing through the refrigetory, which is supposed to be full of water. Fig. 5. is a glass alembic for distillation, fitted with its head and receiver. *a*, is the alembic, *b* the head, *c* the receiver.

Woulfe's apparatus. Fig. 6.

Figure 6. represents a Woulfe's apparatus fitted up for distillation: *a* is a stand, *b* a lamp, *c* a retort fixed above the lamp by means of the ring on the stand, *d* the receiver standing on the support *e*, *f* a tube of safety passing from the receiver to the jar *g*: *h* a tube passing from the jar *g* to the jar *i*. These jars may be continued at pleasure, and the tube from the last jar may pass under a glass vessel standing in a water or mercurial trough, to receive any gas that comes over. Each of the jars contains a quantity of water, into which the tube that enters into it is plunged. In the bend of the tube of safety there is a little water or mercury, to shut out the communication of the external air. The original of this apparatus must be referred to Glauber, who has represented it in his work on furnaces. The improvement introduced by Woulfe was to have a considerable quantity of water in each jar, by means of which, in many cases, a great deal is saved that would otherwise be lost. All the joinings are to be well luted. The tube of safety prevents any bad accident from happening in the course of the distillation. If there happen to be an absorption of air within the apparatus, as is often the case, the external air rushes through the tube of safety and fills up the vacuum. These apparatus are fitted up in a variety of ways by different chemists; but, after the remarks already made, they may be easily conceived by our readers without any farther description.

The other vessels employed in experiments on liquids do not seem to require any particular explanation. They will be easily understood by any person who attends to the properties of the various liquids subjected to experiment.

CHAP. IV.

Apparatus for Experiments on Solids.

Apparatus for experiments on solids.

THE first and most essential piece of apparatus for experimenting on solid bodies, is the furnace. The French have a great advantage over British chemists in the light, cheap, stoneware furnaces, so easily procured in Paris. They are so light as to be easily manageable, and so cheap as not to be beyond the purchase of the poorest experimenter. It is rather surprising that they have not been introduced into Great Britain. They might be constructed with the utmost ease by our potters and crucible makers; and the sale, from the many advantages which they possess, could not but be extensive. When properly hooped with iron on the outside, they would, probably, answer very well for our pit coal fuel.

Furnaces.

Plate CXLIII. Figs. 7, 8.

The best account of furnaces in any English book that we have seen, is in Lewis' *Philosophical Commerce of the Arts.* The practical chemist would do well to consult that excellent treatise. A great variety of furnaces are employed by chemists; but the *wind furnace* may be made to answer almost every purpose. It may be raised to as high a temperature as the blast furnace, by making its chimney of the proper height. We have seen a heat of 160° Wedgewood produced in a very small wind furnace, and iron melted in it with great facility. We shall give a short description of the most improved form of Black's portable wind furnace, the one commonly employed in this country. Figure 7 is an outline of the furnace, and Fig. 8. a section of it. The same letters indicate the same parts in both figures. It consists of an oval iron case, 22 inches high, 20 in its largest diameter, and 15 in its shortest, lined with fire brick or fire clay for about three-fourths of its height from the top, which part forms the body of the furnace, while the under part, which is not lined, forms a very spacious ash pit. *a a*, Is the body of the furnace, which is cylindrical, but a little oblique, that the flame of the fuel may heat the sand more equally than if it were a straight cylinder. The breadth of this cylinder is 8½ inches, and its height 15. The grate *c* lies across the bottom. This fire place has the following openings above the grate: The highest is the large opening at the top, which, when a sand heat is employed, receives the sand pot *i*, and, when this is not wanted, is covered by a thick iron plate lined with clay. The next opening is the elbow of the chimney *f*, which widens as soon as it takes a perpendicular direction, and for the first few inches forms a part of the iron case of the furnace, and is lined with clay. After which it is elongated by an iron tube fitted to it, and not represented in the Figures. The degree of heat is regulated by varying the length of this iron tube. The third opening *e* serves to introduce fuel, and may be employed also to regulate the heat. The fourth opening consists of two small round holes *g g* opposite to each other on the two sides of the furnace. Through them a porcelain or iron tube is occasionally introduced, when it is required to be heated to redness for any particular experiment. The last opening *d* is intended for introducing a muffle. All these openings are furnished with thick brick stoppers and iron plates which slide over them. There are two openings *b b* in the ash pit, which serve to regulate the draught of air, and, of course, to vary the heat of the furnace.

Muffles. Plate CXLIII. Fig. 9. Fig. 9 is a muffle. This is a vaulted flat-bottomed earthen vessel, close at one end and open at the other. It is introduced into a furnace with its open end corresponding to the muffle door of the furnace, and is intended to expose small vessels to heat without being in contact with the fuel. There are usually openings in its sides to allow the entrance of heated air.

Figs. 10, 11. Figures 10. and 11. represent a convenient and cheap blast furnace, contrived by Mr Arthur Aikin from an idea of Dr Lewis in his Philosophical Commerce of the Arts. It consists essentially in two black lead crucibles, one of which *a* is inverted, and the other *b* is placed over it. A hole is bored in the bottom of the crucible *b*, into which the clay stopper *c* (Fig. 12.) is fixed, merely to give firmness. Eight holes are bored in the bottom of the crucible *b*, only two of which are represented in the Figures. Through these holes the air driven in by the bellows, represented in Fig. 10. fixed upon a wooden stand, makes its way to the fuel, and speedily raises a most intense heat. To protect the eyes, it is often necessary to put the crucible *e*, Fig. 13. furnished with the opening *f*, to let out the smoke, over the crucible *b*.

Crucibles. Figs. 14, 15, 16, 17. Figures 14, 15, 16, 17, represent two crucibles, the one triangular, the other circular, with their lids and their supports. These supports are sometimes rolled, as in Fig. 40, and sometimes hollow as in Fig. 41. Crucibles are made of a very refractory clay. The Hessian crucibles are upon the whole the best. The black lead crucibles, made in England, are likewise excellent. They bear sudden heating and cooling well, and they are so soft that they can be conveniently cut with a knife, or saw any way that the experimenter pleases. Of late it is said that micaceous iron ore, or some similar ore of iron, has been substituted for black lead by the manufacturers. This is a grievous fraud, and injures the value of the crucibles most materially. Cast iron crucibles are sometimes used by chemists, but they are not of much value. Crucibles of fine silver are indispensible for the analysis of stony bodies, as silver best resists the action of alkaline bodies at high temperatures. Crucibles of platinum are also indispensible in a good laboratory. They bear almost any temperature, and are but little acted on by most chemical agents.

Mortars. Mortars of various kinds, for pounding solid bodies, are also necessary for the laboratory. There should be one of glass, one of Wedgewood ware, and one of agate. There should also be one of steel, consisting of a hollow cylinder fitted into a flat steel piece. A solid steel cylinder should be fitted by grinding into the hollow cylinder. The hard stone (ruby, for example,) is to be put by little at a time into this mortar, and, by a smart blow with a hammer upon the solid cylinder, it is easily reduced to small fragments. These are ground to an impalpable powder in the agate or flint mortar. The reader will find figures of different mortars, searces, and various other utensils, as files, &c. which we do not think it worth while to mention, in Lavoisier's *Elements of Chemistry*.

Lutes. It may be worth while to say a few words about lutes, which are essential to the practical chemist. Flour, almond-meal, or linseed-meal, make a good enough lute for a common still. They are made into a paste, applied when moist, and allowed to dry. The fat lute answers well for luting retorts and receivers. It is made by beating together pipe-clay and linseed-oil. As it never becomes hard, it is requisite to cover it with linen, and tie the whole firm with a string. The best way is to dip the linen into a hot solution of glue; and to allow the linen to dry after it has been tied on, before beginning the distillation. For coating glass retorts, a mixture, of pipe-clay, sand, horse-dung and glue, made into a thin paste, answers well. The retort is dipped in, and after the first coating is dry, it is dipt again. This is continued till the coating is sufficiently thick for the purpose required. A very good lute for those joinings that are to be exposed to a strong heat is a mixture of clay and borax. We have also used successfully a mixture of clay, sand, and litharge. But this last lute is not so much to be depended on. Many other lutes are to be found in chemical books; but those we have mentioned are the ones which upon trial we have found best.* (c)

CHEPEWYANS. See CANADA, p. 343.

CHEPSTOW, a town of England, in Monmouthshire, situated near the mouth of the river Wye, partly in a deep hollow, but chiefly on the steep side of a hill. The houses are tolerably built, and the streets, though irregular, are broad and well paved.

Chepstow was formerly surrounded with walls, and was defended by a strong castle, which seems to have been built in the time of the conquest by William Fitz-Osborn, Earl of Hereford. The remains of this stupendous pile occupy a large tract of ground, and extend along the brow of a perpendicular cliff, of which its walls in many places appear to form a part. The river Wye runs at the bottom of this cliff, and flowing through some of the arches defends it on one side, while on the land side it is protected by an immense moat, and by the lofty bastion towers by which its walls are flanked. The grand entrance on the east, which is by a circular arch between two round towers, is a fine specimen of the early Norman architecture. This entrance leads into the first court, containing the grand hall, kitchen, and other apartments. The second court, which is now used as a garden, is entered from the first by a gate at the side of a round tower; and in the third court, which is entered from the second, is situated the roofless chapel, with pointed arched windows, and tiers of semicircular arches along the wall. A winding staircase at the south western extremity of the third court conducts to the battlements, and the entrance to the fourth court is by a sally port in the wall. The most interesting part of this castle is the grand tower at the south eastern angle of the first court, in which Henry Martin, one of the murderers of Charles I. was confined for thirty years. This tower has generally been represented as a dark and miserable dungeon, but Mr Coxe's description completely contradicts this opinion. "The first story of this tower, (says he,*) contains an apartment which was occupied by himself and his wife; above were lodgings for his domestics. The chamber in which he usually lived is not less than thirty-six feet in length, and twenty-three in breadth, and of proportionate height. It was provided with two fire places, and three windows, two of which appear to be the original apertures, and the third was probably enlarged for his convenience."

The present parish church of Chepstow consists chiefly of the remains of the old priory for Benedictine monks. Within the church, the circular arches of the nave still exist, and the remains of the ancient choir and cross aisle may be traced by the foundations on the outside. The former entrance was by a beautiful semicircular arched doorway, decorated with fine mouldings. A smaller arch, ornamented in the same way, is on each side of the doorway.

The bridge over the Wye, half of which is in Gloucestershire, has a level floor, and was formerly supported by timber piers about forty feet high. It underwent, however, a thorough repair in 1791. The wooden piers still remain in the Gloucester side, but on the other side they have been replaced by stone piers. The massive central pier which separates the two counties is of stone. The wooden piers present a very narrow surface to the stream.

There is an ebbing and flowing well in a garden in Bridge-street, remarkable for the excellence of its water. It is about 14 feet deep, and frequently contains 14 feet of water. A little before high tide, the water begins to subside; at high tide it becomes perfectly dry, and soon after the ebb the water returns. The flow of the well is in no respects affected by wet and dry weather.

As the channel of the river Wye is very narrow in proportion to that of the Severn, and is confined by perpendicular rocks, the tide flows up to the town with great velocity, and sometimes rises to the height of fifty-six feet. Mr Coxe found, that at high water the depth of the river was forty-seven feet three inches, the distance from the surface of the water to the floor of the bridge six feet. As the tide once rose to a notch in the rail two feet ten inches above the floor of the bridge, it follows that the highest tide was fifty-six feet one inch.

* Coxe's *Historical Tour in Monmouthshire*, p. 378.

Chepstow is the port for all the towns on the rivers Wye and Lug, and vessels of 600 tons burden are built for the Baltic trade. The inhabitants, who are full of activity and enterprise, carry on a considerable trade in the corn and provisions which are produced in the surrounding country. The merchants import their own wines from Oporto, and from Norway and Russia they receive deals, hemp, flax, pitch, and tar, with which they supply Herefordshire, and the eastern part of Monmouthshire. Great quantities of timber are sent from Chepstow to Portsmouth, Plymouth, Deptford, and Woolwich; grain is exported for the Bristol market; and oak bark, cider, coals, grindstones, millstones, and iron, to several parts of Ireland, Liverpool, and other places. Convenient quays are erected on the banks of the Wye for the numerous vessels by which it is frequented.

About two miles to the west of Chepstow is the celebrated mansion of Piercefield, remarkable for its beautiful and picturesque scenery. The following Table contains the statistical information in the population returns in 1811, for the parish of Chepstow.

Number of inhabited houses, ...	421
Number of families, ...	451
Houses building, ...	9
Houses uninhabited, ...	8
Families employed in agriculture, ...	3
Families employed in trade, manufactures, and handicraft, ...	180
Families not comprehended in any of these classes,	268
Number of males, ...	1,158
Number of females, ...	1,423
Total population, ...	2,581

CHEQUE. See CHECK.

CHER, one of the departments of France, which derives its name from the river Cher, and is formed from the higher Berri. It is bounded on the north by the department of Loiret; on the west by the department of the Loire and Cher, and the department of the Indre; on the south by the department of the Allier; and on the east by the department of the Nievre. The superficial extent of the department is about 7385 kilometers, or 468 square leagues of 2000 toises, which is equal to about 1,450,134 square acres.

The principal productions of this department are grain of all kinds, very fine hemp, flax, wines, among which the red wines of Sancerre, and the white wines of Pouilli are the most famous, fruits, honey, wax, wool which is highly esteemed; mines of coal and ochre; quarries of marble; mines of iron, which supply fourteen furnaces and eighteen forges; salmon, and all kinds of fresh water fish. The navigable rivers are the Cher, which is navigable from Vierzon to the Loire, during six months of the year, the Loire, and the Allier, which bound the department on the east. A canal was begun, to form a communication between the Loire and the Cher, by means of the river Erve. The forests of this department occupy 145,000 hectares, about 102 of which belong to individuals, and the rest to the communes and the nation. The contributions, in the year 1803, amounted to 1,742,031 francs. Population, 218,297. Bourges is the capital of the department. The other towns are St Amand and Sancerre. See BOURGES. (*w*)

CHERASCO, QUERASCO, or KAIRASC, a town of France in the arrondissement of Savillan, and department of Stura, situated on a mountain near the confluence of the Stura and the Tanaro. This town, which is derived from the Celtic, *kair* or *kaer*, a city, appears to have been inhabited in the time of the Romans, from the great number of Latin and ancient inscriptions which have been discovered. The town is well built, and the streets are spacious and open. Some of its parish churches, which amount to seven, are very fine. It has also several palaces, in one of which, belonging to the Count Salmatoris, was signed the treaty of 1631, called the treaty of Cherasco; and also the late treaty, by which this part of Italy was added to the French empire. Cherasco was fortified in the modern style, with fosses, bastions, and out-works, by Christina of France, Duchess of Savoy. Epidemic diseases prevail here in a great degree, and are supposed to be occasioned by the exhalations from the rivers Stura and Tanaro. On this account, the town is said, by Denina, to have only about 4000 inhabitants, though, according to the returns of the Bureau de Poste, given in the *Almanach du Commerce* for 1811, the population amounts to 11,200. It carries on a considerable trade in grain, wines, and silk. A fair, which continues for three days, is held on the 18th June; and another for two days on the 14th November. Cattle and victuals are the principal articles of sale. E. Long. 7° 41′, N. Lat. 44° 33′. See Denina's *Tableau Historique Statistique et Morale de la Haute Italie*, p. 53. Paris, 1805. (*π*)

CHERBOURG, a sea-port of France, in the department of the Channel, is situated at the bottom of a large bay, between Cape la Hogue and Cape Barfleur. The principal objects of curiosity are the harbour, the Salle de Spectacle, the garden called Tivoli, the public baths, and the Promenade de L'Abbaye. The road is capable of holding from 500 to 600 vessels; and when the improvements upon the harbour are completed, it will become one of the strongest and safest ports in Europe. The establishment of tides for this port is 9 h. 30 min. Vessels of 900 tons can be admitted at high water, and those of 250 tons at low water. Woollen and cotton stuffs are manufactured here in considerable quantities. There is a manufactory of plate glass, and also a common glass-work. Small vessels for the coasting trade are also built here. The principal articles of commerce are grain, apples for cider, flax, butter, salted beef and pork, and soda of Varech for the glass-works. Population, 14,000. Its position, according to late astronomical observations, is in W. Long. 1° 37′ 9″, and N. Lat. 49° 38′ 31″. (*w*)

CHERLERIA, a genus of plants of the class Decandria, and order Trigynia. See BOTANY, p. 218.

CHEROKEE INDIANS. See AMERICA.

CHERSO, one of the largest islands in the Gulf of Venice, is situated on the coast of Croatia, near to the island of Osero, from which it is separated by a narrow strait, about 15 miles long, and from two to five in breadth. This island is 150 Italian miles in circumference, and gives its name to the capital town. The climate is very wholesome, and the soil, though remarkably stony, is fertile, and watered by a number of rivulets. It produces very little corn; but its cattle, honey, wines, and oils are in sufficient quantities to be exported, and held in much estimation. This island is remarkable for the extreme smallness of its horses, which are, however, strong and spirited, and of a delicate and graceful form. There is here a lake about seven miles in circumference, which abounds in fish, and which is said by the inhabitants to contain several species that have hitherto been found only in the sea. This circumstance has given rise to the opinion, that it has a subterraneous communication with the ocean. The capital of the island, which was anciently called Crispa or Crexa, is said to contain about 4000 inhabitants; and M. Cassas represents them as almost savages. This island, according to some accounts, supports 70,000 sheep, and contains about 11,000 inhabitants. See M. Cassa's *Travels in Istria and Dalmatia.* (x)

CHERSON or KHERSON, KOSLOF or GUSL-OVE, a town of Russia, in the province of Catharinenslaf, is agreeably situated on a small eminence, at the bottom of which runs the Dnieper. The width of this river is about seven versts, and it forms several little isles, covered with shrubs. Cherson is about 14 versts below the mouth of the Ingulitz, and 40 versts above the river Bog. This town was built by the Empress Catharine II. in 1777, and the foundation stone was laid by General Annibal. It is constructed chiefly of hewn stone, which is found at the mouth of the Ingulitz, a distance of almost 15 miles from the town; and it has been considerably improved by Prince Potemkin, who was very partial to the place. It is now, however, gradually sinking into decay, from the unhealthiness of the situation, and from the preference given to Odessa, the air of which is remarkably pure and wholesome. The ancient city stood some miles to the south-west of the spot where the town of Swastopl now stands. The principal public buildings are the arsenal, the fortress, the cathedral, and the admiralty house. The former is a large and interesting edifice, built by Prince Potemkin, and contains a monument to his memory. The fortress, which was also erected by Potemkin, is built in a good style of architecture, of a kind of porous, but durable lime-stone. It occupies a great extent of ground, has a double fosse, and contains some good barracks. The other objects deserving of notice in this place, are the immense flight of steps leading down to the Dnieper, and the battery of stone which is built at the level of the water. The last war of Russia with France has almost annihilated the commerce of Cherson. Before that event, the exportation of corn, hemp, and canvas was very considerable. In 1786, the commerce of Cherson employed 131 vessels, viz. 92 belonging to the Turks, 32 to the Russians, and 7 to the Austrians. The imports consisted of fruits, wines, fish, and household furniture. The exports were soap, wheat, hemp, flour, iron, wool, flax, cordage, tobacco, and wood. It appears, however, impossible, from the difficulty of navigating the Dnieper, that it could ever be a place of great commercial importance. The entrance of that river is extremely narrow; and sometimes north-east winds leave it so full of shallows, that its depth is not greater than five feet. The sands are also continually shifting, which renders the navigation so dangerous, that when Dr Clarke visited the place in the end of 1800, ships were rarely seen in the harbour.

Baron Campenhausen, however, who visited Cherson later than either Dr Clarke or Reuilly, informs us, that the trade had again revived, and that a number of French and Austrian ships, also 300 or 400 Greek barks, were lying in the harbour, the latter of which were laden with Turkish leather, honey, wax, Greek wines, soap, cloth, iron, &c. Several men of war and merchant vessels are built in the docks, which, on account of the bar, are floated down to the Liman, (or swampy fresh water lake,) on camels as at Petersburg. The docks belonging to the crown are situated along the Dnieper. The grand depot of timber is on the opposite bank,* and there is a rope-walk, where excellent ropes and cables are made. The merchants harbour is at the end of the town, and the quay is built on piles. Cherson has a lazaretto which is situated on one of the isles of the Dnieper; but, in consequence of the quarantine being performed at Odessa, where ships are obliged to unload, it is now useless. No foreign merchants of any consequence reside at this port; they transact their business by clerks and supercargoes. Immense herds of oxen are fattened on the vast plains near Cherson, and are sold at low prices. Corn is generally cheap and plentiful, and water melons grow here as large as in Italy. Fuel is entirely supplied by reeds, of which an inexhaustible quantity is produced in the shallows of the Dnieper opposite to the town. They are so tall and strong, that rails, and sometimes temporary houses, are formed of them, and they afford shelter to various kinds of aquatic birds, some of which are of great beauty. This town is badly supplied with water, which is brackish: that which the inhabitants make use of for drinking is brought from a great distance.

Cherson is interesting, as being the place where the philanthropic Howard terminated his career of humanity and usefulness on the 20th day of January, 1790. He was buried in the spot he had himself chosen, in the desert near the village of Dauphigny, about five versts from Cherson. A monument is erected over him, (contrary, however, to his express desire,) consisting of a brick pyramid or obelisk, but without any inscription. Cherson is celebrated also as containing the burial place of Prince Potemkin. He died on the 15th of October, 1791, on the road from Yassy to Nicholaef. Being in want of air, his servants had removed him from his carriage and placed him in a *ditch* that he might be supported by its sloping sides, and in this situation he actually expired. The corpse was soon after brought to Cherson, and buried in the small church belonging to the fortress; and it affords a melancholy, but striking instance of the instability of human greatness, that this most powerful and illustrious of all the imperial favourites, has not now even the poor distinction of a grave. The coffin has disappeared, and the body is supposed to have been taken up and thrown into the ditch of the fortress by the Emperor's command. Great inconvenience is experienced at Cherson from the prodigious clouds of dust and the immense quantity of mud in winter. There are also innumerable swarms of gnats, which are produced in the marshes. Wild boars are frequently seen swimming among the small isles of the Dnieper. In the year 1783, the population of Cherson is said to have amounted to 40,000; but in 1803, when it was visited by M. Reuilly, it contained only 10 or 11,000. East Long. 47°, North Lat. 46° 42′. See Clarke's *Travels*, vol. i. p. 598; Scherer, *Histoire raisonnée du Commerce de la Russie*, tom. ii. p. 33. Paris 1788.; Reuilly's *Travels in the Crimea*, chap. xi.; and Baron Campenhausen's *Travels through several provinces of the Russian Empire.* (x)

CHERSONESUS. See CRIMEA, JUTLAND, THRACE, &c.

CHERTSEY, a town of England, in Surrey, is pleasantly situated within a quarter of a mile of the Thames. The bridge over the Thames was built by Mr Payne in 1785, and consists of seven arches. It is built of Portland stone, and cost L. 13,000. A commodious workhouse, and a good charity school, are the only public institutions. In the *porch house*, at Chertsey, the poet Cowley ended his days. This is supposed to be the spot where the Romans, under Julius Cæsar, crossed the Thames. The river was defended by stakes; and Beda informs us that great stakes, as big as a man's thigh, were to be seen in the 8th century. There was formerly an abbey here, in which was deposited the corpse of Henry VI.; an elegant mansion was built out of the ruins of this abbey, by Sir Henry Carew, in the reign of Charles II. In this town are considerable manufactures of malt, thread, iron hoops, and bricks, which are sent down the Thames to London. The parish contains 652 inhabited houses; 697 families, of which 239 are employed in agriculture, 191 trades and manufacture, and 267 which are not included under any of these heads. The population in 1811 was 3629. See Manning's *History and Antiquities of the County of Surrey*, continued by William Bray, Esq. (π)

---

* Timber is dearer here than in the north, on account of the cataracts of the Dnieper, which impedes its being floated down.

CHESAPEAK BAY. See MARYLAND and UNITED STATES.

CHESHIRE, one of the western counties of England, is bounded on the north by the rivers Mersey and Tame, which separate it from Lancashire; on the east by the counties of Derby and Stafford, in which direction the division is marked chiefly by a chain of hills, and by the rivers Goyt and Daner; the southern side unites with Shropshire and Flintshire; and the western border is skirted by Denbighshire, Flintshire, and the estuary of the Dee. The dimensions of the county are estimated by Mr Wedge at about 22¼ miles on a medium in breadth; and in length, from W. S. W. to E. S. E. nearly 40 miles. This statement, however, is plainly inaccurate, the extent of the county, from Bretland Edge, on the Yorkshire side, to Kiddington Green, bordering on Flintshire, being upwards of 50 miles. Its form is rather inclined to an oval, with two projecting necks of land; one about 20 miles in length and 6 in breadth, running out into the Irish Sea, between the estuaries of the Dee and Mersey, and called the Wirral: the other is included in the Macclesfield hundred, and extends from Stockport, between the counties of Derby and York, about 15 miles in length, rarely exceeding 4 miles in breadth. This county is in general flat; but some considerable hills rise near its eastern borders, which are connected with those of Derbyshire and Staffordshire, and extend about 25 miles in length, from Congleton to the N. E. corner of the county. An interrupted ridge of high ground, composed entirely of sandstone, also crosses it from N. to S. on the western side, extending from Frodsham to Malpas, and including the high grounds of Delamere Forest, the hill of Beeston, and the Peckforton hills. There are a few other hills about Macclesfield, and some on the Shropshire side. A chain runs north and south through the peninsula of Wirral. The rest of the county is nearly level; and the principal part of it consists of arable, meadow, and pasture land. The soil is various; but clay, sand, black moor or peat, seem to predominate, the subsoil being commonly clay or marl. The most prevalent stone of the county is the red grit rock, of which most of the towns and villages are built. Large woods are rare; but as hedge rows abound in the generality of farms, the quantity of timber that is produced is considerable, particularly of oak-trees, from which the tanners obtain a valuable supply of bark.

The tenure by which land is held in Cheshire is almost universally freehold; yet, in some manors, there are a few copyholds, or what may be denominated customary freeholds, paying fines and rents certain. Leasing for lives, which was formerly a very constant and general practice, is yet continued by a few landholders; but the most common term of leases is 11 years, with a restriction on the tenant to a certain quantity of tillage, (usually about ⅓ of his farm,) and a particular rotation of crops. The extent of farms is on the average from 150 to 300 acres: some few contain upwards of 500.

The principal object of attention with the Cheshire husbandman is the dairy. In former periods, the county was much celebrated for its produce in wheat; but in later times it has been noted chiefly for its cheese. Strabo and Pliny affirm, that the art of cheese-making was introduced into it by the Romans, but this is improbable from various circumstances; and we are certain that the Roman armies on the continent received a great supply of cheese from this county soon after they had secured the possession of it. The quality and flavour of the Cheshire cheese are well known: the following are some of the principal particulars as to the mode of its manufacture. In a dairy farm of 100 acres, from 10 to 14 acres are under oats; from 6 to 8 are occupied with fallow-wheat, and the like quantity is laid out in summer-fallow; the remainder is appropriated to pasture and hay, the amount of the latter being about 12 acres. The judicious dairy farmer is very scrupulous in the breeding and rearing of calves, and in the management of his cows, both during the summer and the winter. The quantity of cheese made annually from each cow varies from 50 to 500 or more pounds; the produce depending in a considerable degree on the nature of the land, the quality of the pasture, and the mode of wintering: in general, the average may be stated at about 300 lbs. The quantity of milk, according to this estimation, yielded daily by each cow is about 8 quarts, which is commonly supposed to produce one pound (16 oz.) of cheese. The Cheshire cheese is generally made with two meals' milk; but often towards the latter end of the season, (which continues nearly 22 weeks,) with 4, 5, and 6, the cheeses being usually made very large. The most common size is 60 lbs.; a weight susceptible of every excellence to be found in the cheese of this county. Of those large cheeses, two are made in some of the dairies daily. The evening's milk being preserved till next morning, it is skimmed, heated, and incorporated with the new milk, when the whole, together with the cream, being mixed in a large tub, and the proper quantity of rennet and colouring being added, it is left for about 1½ hours to coagulate. When the cheese is come, or the milk is properly coagulated, the curd is broken into very small particles, which are left to subside, and the whey is poured off. This process is repeated till the whey is nearly expelled. Then the curd is placed in a vat, and occasionally sprinkled with salt, of which some dairy women use about three handfuls to a cheese, making it a rule to put the greatest quantity near the middle. The vat is filled very full, and the whey repeatedly squeezed out, before it is placed in the press, as it is very material to expel all the whey, keeping the vat at the same time quite full of curds. The cheese is commonly taken twice or thrice from the vat, to place fresh cloths, pare off the edges, and turn it; and sometimes it is immersed in hot whey, which is supposed to harden its coat. After remaining in the press two or three days, it is next conveyed to the salting house, where it is put in a salting tub, in which having continued for about three days more, it is next placed on the benches for about eight days, being well salted all over, and turned every day. For six or seven days subsequent to this process, it continues to be turned twice daily. Then it is washed in warm water, wiped dry with a cloth, and when dry, smeared over with whey-butter, and placed in the warmest part of the cheese-room, where it is left to acquire the proper age and consistence.

The principal mineral productions of Cheshire are salt and coal. The former is more abundant in this county than in any other part of England; and the immense trade carried on in it, with the vast revenue which it affords, render it an object not only of local, but even of national importance. The places which have been most noted for their salt-works are Nantwich, Middlewich, Winsford, and Northwich. The salt-work at Nantwich was once very considerable; but, in consequence of the superior advantages in respect to situation belonging to other towns, it has now been deprived of a great portion of its former trade. It was expected that that trade would have been renovated in some degree, from the termination of the Chester canal in a bason near to this town; but the expectation does not appear to have been yet realised. Mr Pennant conjectures, that it was here that the native Britons first saw white salt, whence they gave to the place the name of Heldd Wen, or the White Brine Pits. Middlewich derives its name from its central situation between the Wiches or Salt-towns. The salt manufactured there is prepared from brine springs, well saturated. The quantity at this time is not great; but were a demand to offer, it might easily be increased. The great seat of the salt trade in Cheshire at present is Northwich. Here the salt is made from brine springs, and also from the natural rock. This, as it is the chief of the salt towns, is the only one indeed, which, in addition to its brine springs, possesses mines of rock-salt: at least there seem strong grounds for believing, that the beds of rock-salt here are perfectly distinct from any others in the salt district, forming what the Germans would call *liegende stöcke*, lying bodies, or masses of the mineral. It is to be remarked at the same time, that the brines met with in this district are very generally formed, by the penetration of spring or rain waters to the upper surface of rock-salt. The average strength of these brines appears to be much greater here than in any of the springs that occur in Hungary, Germany, or France. In the places where all the principal salt works are situated, they contain between 25 and 26, and in some instances even more, of the pure muriate of soda. The earthy salts held in solution together with this muriate, are principally muriate of magnesia and sulphate of lime, the quantity of which varies in different springs, from $\frac{6}{10}$ to 2 or $2\frac{1}{2}$ per cent. The springs of Cheshire were known to the Romans, and had the common name of Salinæ. The mode in which they turned them to account was very similar to the process now employed, and this process, it is supposed, they communicated to the natives. There is a tradition moreover, that the rock, as well as the brine-pits, were wrought in the time of the Romans. In modern times, however, the discovery of this valuable mineral does not appear to have been prior to the year 1670, since which time it has been found in various places in the vicinity of this town.

The rock salt occurs from 28 to 48 yards beneath the surface of the earth. The first stratum or mine is from 15 to 21 yards in thickness. It very much resembles in appearance brown sugar candy, is perfectly solid, and so hard as not to be broken, but with great difficulty, by iron picks and wedges. Of late, the workmen have been accustomed to blast it with gunpowder, by which means they loosen and remove many tons of it together. Beneath this stratum there is a bed of hard stone, consisting of large veins of flag, intermixed with some rock-salt, the whole from 25 to 35 yards in thickness. Under this bed is a second stratum or mine of salt, from five to six yards thick, many parts of it perfectly white and clear as crystal, others browner; but all purer than the upper stratum, yet reckoned not quite so strong. Only these two distinct beds of the fossil salt have been met with at Northwich; but it has been ascertained, that the same limitations do not exist throughout the whole of the salt district, three distinct beds at least being found in some situations, separated in like manner from each other by intervening strata. The great body of the rock-salt, both in the upper and the lower beds, is composed of crystals of muriate of soda, intimately mixed with certain proportions of clay and oxide of iron, containing likewise small proportions of certain earthy salts.—Throughout, at the same time, particularly in the lower strata of the rock, there are found separate crystalline concretions of muriate of soda in a purer state, variously disposed, sometimes occurring distinctly in the cubical form, in other places in masses of larger size, and irregularly shaped. Above the whole mass of salt lies a bed of whitish clay, which has been used in the Liverpool earthen-ware; and in the same situation there is found also a quantity of gypsum.

Rock-salt pits are sunk at great expence, and are very uncertain in their duration, being frequently destroyed by the brine springs bursting into them, and dissolving the pillars that support the roof; through which, then, the whole work falls in, leaving vast chasms in the surface of the earth. In forming a pit, a shaft or eye is sunk, similar to that of a coal-pit, but more extensive. When the workmen have penetrated to the salt rock, and made a proper cavity, they leave a sufficient substance of the rock (generally about seven yards in thickness) to form a solid roof; and as they proceed, they hew pillars out of the rock, also, to sustain the roof. Gunpowder is then employed to separate what it is meant to raise, which is conveyed to the surface in huge craggy lumps, and is drawn up above ground in capacious baskets made for the purpose. When well illuminated, the crystalline surface of the roof, pillars, and sides of a large pit, make a glittering and magnificent appearance, which seldom fails to have a very impressive effect on the mind of a stranger. Fresh air is conveyed from the mouth of the pit by means of a tube, with a pair of forge-bellows fixed to it; and thus a perpetual current is preserved between the outer and inner air. The pits, at the greatest depth, are dry, and of an agreeable temperature.

The largest rock-salt pit that is now worked in Cheshire, is one in the township of Wilton. This has been excavated in a circular form to 108 yards in diameter; its roof is supported by 25 pillars, each three yards wide at the front, four at the back, and six yards in the sides. Each of these pillars contains 294 solid yards of rock-salt, and the whole area of the pit, which is 14 yards hollow, includes 9160 superficial yards, or little less than two acres of land. The quantity of rock-salt delivered annually from the pits, in the neighbourhood of Northwich, is from 50,000 to 60,000 tons. Hardly more than $\frac{1}{4}$th of this is refined in England, the remainder being exported to various parts of the continent. The salt is conveyed down the Mersey, in vessels from 50 to 80 tons burthen, to Liverpool, where it is reshipped for foreign countries, or kept to be refined.

Besides the great quantity of salt obtained from the rock, an immense weight is supplied by the brine pits, not less than 45,000 tons annually, being manufactured at this town, or in the vicinity. The usual depth of the springs is from 20 to 40 yards. These are situated on a hill at some distance. The briny stream is raised by a steam-engine, and conveyed through very long troughs to the brine-pits. The process of extracting the salt is accomplished by heating the liquor in iron pans, of 20 or 30 feet square, and about 14 inches deep. When it boils a light scum rises to the top, which is taken off, and the liquor reduced to a lower degree of heat: the steam arising is made to evaporate as quickly as possible; and the salt collecting into crystals forms a crust on the surface, which, sinking afterwards to the bottom of the pan, is thence removed once or twice in every 24 hours. The revenue arising from the salt of this county is considered of so much consequence, that a particular board is appointed for its collection and management, quite independent of the excise and customs. The quantity of it made annually for home consumption has been stated to amount to more than 16,000 tons, while the average of the quantity sent to Liverpool for exportation has not been less than 140,000 tons. See Holland's Sketch of the Natural History of the Cheshire Rock-salt District in the *Transactions of the Geological Society*, vol. i. p. 38.

Coal, and various other valuable minerals, are found in abundance in different parts of Cheshire. A small quantity of copper ore has been found in the Peckforton hills; and lead, copper, and cobalt ores occur at Alderley Edge, in the eastern part of the county.

Besides the staple produce of Cheshire, viz. its cheese and its salt, the principal articles of its manufacture consist of silks, cotton, and linen goods. The cotton trade particularly, which has of late been extended into it from Lancashire and some of the bordering counties, seems now, next to the manufactures mentioned, to constitute even the most considerable and flourishing branch of its trade. Manufactures of leather, ribbons, thread, gloves, buttons, and shoes, are carried on at Nantwich, Macclesfield, Congleton, Knutsford, and some other places. A considerable portion of the industry of the county has been laid out also in working its mines, and in increasing the value of that important description of produce. Chester is a great mart for Irish linens. Other commodities imported there are wood, hides, tallow, feathers, butter, provisions, &c. from Ireland; groceries from London; timber, hemp, flax, iron, and tallow, from the Baltic; kid and lamb skins from Leghorn; fruit, oil, barilla, and cork from Spain and Portugal, and from the latter a large quantity of wine, which is indeed the principal article of foreign import. The exports are coal, lead, lead ore, calamine, copper-plates, brass, cast-iron, and vast quantities of cheese.

It is of great consequence towards facilitating the trade of this county, that it is so advantageously situated by nature in respect to the means of water-carriage, and it has been not less fortunate for it, that the means thus placed within its reach of melioration and general benefit have been so assiduously and so wisely improved. Most of the rivers and streams which wind through this county direct their currents northward, and empty themselves into the Mersey or the Dee. The former of these principal rivers divides Cheshire from Lancashire for a course of nearly sixty miles; for about 35 of which, from Liverpool to the mouth of the river Irwell, it is navigable for vessels of considerable burthen. Deriving its source from a conflux of small streams at the junction of the county with Derbyshire, and flowing in a westerly direction, it receives in its course the waters of the Goyt, the Tame, the Bollin, the Irwell, and the Weaver; after its junction with the latter of which, it swells into a broad estuary, and taking a north-western course, soon unites with the Irish channel. The Dee originating in the mountainous district of Merionethshire, and having formed the large lake of Pemble-mere, passes afterwards through a series of very picturesque and grand scenes, till it approaches the western border of the county, to which it forms a boundary from Worthenbury to Aldford. It then passes on to Chester, the walls of which city it nearly encircles, and flows thence to the west through an artificial channel, which was formed at an immense expense by a body of gentlemen, called the River Dee Company. This river forms also a large sandy estuary between the county of Flint and the hundred of Wirrel, and joins the Irish sea about 14 miles north-west of Chester. The Weaver, deriving its source from Ridley Pool, close to Cholmondeley Hall, passes the towns of Nantwich, Minshull, Weaver, Winsford, and Northwich, where it is joined by the Dane from the northern parts of Staffordshire, and two or three other streams from the central parts of the county. Hence it proceeds to Wareham, Acton Bridge, and Frodsham, receiving during its progress several tributary streams, and falling ultimately at the last mentioned point into the swelling bason of the Mersey. Between this place and Winsford it has been rendered navigable by means of several locks. The plan by which this was effected deserves notice, as a memorable instance of local patriotism. The gentlemen of the county observing the great expense of land carriage from the salt-towns, to Liverpool and other maritime places, obtained, in 1720, an act of parliament for the purpose of rendering the Weaver navigable, and empowering them to raise on that account a subscription of L.49,000. The subscribers were to receive 5 per cent. on the principal, and 1 per cent. for the risk, and also certain instalments arising from the tonnage of vessels on the river, till the money advanced was reimbursed; but afterwards the whole amount of the tonnage, deducting only the charges of necessary repairs and management, was to go to the support of public bridges within the county, and to other public useful purposes. Every vessel navigating the river pays one shilling per ton, and the receipt has amounted in some years to L.8000. The debt has consequently been paid off for some time; and this lucrative revenue having been left free, has since been applied to several considerable uses both in town and country. The length of the navigation is 20 miles, in which course it has a fall of 45 feet 10 inches, divided between 10 locks. About 120 vessels, from 20 to 100 tons burthen, are constantly employed here, and are principally occupied in carrying rock salt downwards, and taking up coals in return.

Besides the Weaver navigation, the county of Cheshire is intersected by portions of four canals, which afford the means of a very constant and cheap intercourse of traffic between the towns of Chester, Liverpool, Manchester, the north of England, Staffordshire, Shropshire, and other counties. For forming the Chester canal, after a previous unsuccessful application, an act of parliament was obtained in 1772, with this singular restriction, that the intended canal should not unite or communicate with the Staffordshire canal at Middlewich. It commences at the river Dee, on the north side of Chester, and passing Christleton, Waverton, Hargrave, and the north of Beeston castle, proceeds thence to Nantwich. The branch of the Duke of Bridgewater's canal, which runs through about 20 miles of this county, enters it to the east of Ashton, leaving it again at Runcorn Gap, where it flows into the Mersey. The act for forming this navigation was obtained in 1761; and the whole of it, to the extent of 29 miles, was completed in five years. It has been carried across the Mersey, near Ashton, by an aqueduct bridge; and farther to the west it crosses the Boltin, which running in a tract of low meadows, a mound of earth was raised over this valley to a length, breadth, and height truly stupendous. By these means the water is kept on a level to its egress at Runcorn, where it is precipitately lowered 95 feet by a series of locks of admirable construction. Previously to the formation of this canal, the river navigation from Manchester to Liverpool was 12 shillings per ton, and land carriage 40 shillings; but the rate of conveyance by the canal is only six shillings per ton. Besides the numerous barges which ply here for the carriage of commercial articles, boats on the model of the Dutch treckschuyts have been constructed for the accommodation of passengers, which afford the means of a very cheap and pleasant intercourse between Liverpool and Manchester, and the intervening places. The Grand Trunk canal branches off from the Duke of Bridgewater's at Preston-Brook, and passing Northwich and Middlewich, leaves the county on the south side at Church Lawton. At Preston-on-the-Hill it passes through a tunnel 1241 yards long, 17 feet 4 inches in height, and 13 feet 6 inches wide. A portion of the Ellesmere canal also crosses the western corner of this county, entering it at Palford; and after uniting with the Dee at Chester, crosses the hundred of Wirral for about 9 miles, and then joins the Mersey, thus opening a short and easy passage between Chester and Liverpool.

Besides the several rivers, more or less considerable, which flow through the county of Cheshire, and the canals formed in it, it abounds also with broad sheets of water, denominated meres, lakes, and pools. The principal of these are Oak mere, Rosthern-mere, Mere-mere, Tatton-mere, Comber-mere, Broad-mere, and Bag-mere, Petty-pool, Rookery-pool, and Ridley-pool. Most of these waters abound with fish. There occurs also within the county a spring of mineral water. This is situated in the vicinity of Stockport, and seems to flow from a coal-mine or a bed of iron-stone. Some years ago, when it was first discovered, it was much frequented, as being supposed to afford a remedy for weak eyes and some other disorders. In consequence, however, of an ill-founded prejudice which has since arisen against it, that it occasioned jaundice, it has now been in a great measure altogether abandoned, and has been not less cried down and reviled than it had previously been held in estimation.

In the county of Cheshire there occur various examples of the most sublime and splendid scenery, as well as numerous brilliant prospects. About two miles southward of Tarporley, a small but pleasant town in this district, rises the great insulated rock of Beeston, which is composed of sandstone, is very precipitous on the one side, and on the other slopes gradually downward to the general level of the country. It is nearly 366 feet in height, and commands a very extensive and pleasing view of Chester, and of a great portion of the surrounding country. On the west of this rock are the stately ruins of the far-famed Beeston castle, erected in 1220, by Randle Blundeville, Earl of Chester, which enclosed a space of from four to five acres, and was once proverbial for its almost impregnable strength. The Car Tor, in the vicinity of Mettram, is a very singular precipice of the perpendicular height of about 80 feet, and covered over the summit and sides with oak trees. From its top vast rocks are pendant, which seem to threaten every thing beneath with destruction. The face of the precipice exhibits various strata of rock, coal, or slaty matter, and free-stone, all disposed with considerable regularity, while between it and the opposite and well-wooded hills of Derbyshire, the Mersey, hurrying along its craggy bed, contributes greatly to the grandeur of the contiguous scenery. Weston, in the neighbourhood of the same river, where it joins with the Weaver, is a retired and consequently little noticed, yet really a very beautiful village, environed with several of the most striking features of a luxuriant and highly pleasing natural combination of images and prospects. The Dee, the other great river of this county, is not less without its share of similar embellishment; and it may have been owing, not less perhaps to this circumstance, than to the opinion entertained as to the sacred and purifying nature of its waters, that this river was held in so great veneration as we know it to have been by our British ancestors.

Cheshire contains a great number of considerable towns and villages †. It is also agreeably diversified by the occurrence here and there of a fair proportion of gentlemen's seats, of every degree of antiquity, as well as connected with every variety, as to degrees of wealth and disposition of mind in the proprietors, and consequently varying themselves in an equal degree as to magnificence, taste, and decorations. The county may also lay claim to its full share in the vestiges of an ancient consequence, whether more recent or more remote, foreign or domestic, as well as both of a more general and of a more local nature. While it continued subject to the Romans, this county was included by that people in the division of the country which they named *Flavia Cæsariensis.* Kinderton, in the vicinity of Middlewich, according to the investigation of Mr Whitaker, appears to have been the *Condate* of that people; and various other monuments occur in different parts of the county, indicative of its being held in possession at one period by this race of conquerors. On the final departure of that people from the island, it, with the rest of the country, reverted of course to the Britons, who continued to possess it till about the year 607, when it was conquered by Ethelfreth the Saxon king of Bernicia, who defeated the army of Brochmael Yocithroe, king of Powys, near Chester. On this occasion, Ethelfreth is said to have slain 1200 defenceless monks, whom Brochmael had called from the neighbouring monastery of Bangor, and stationed on a hill in the vicinity, that they might assist him with their prayers. It was afterwards wrested from Bernicia by the Mercians, and continued a part of their kingdom till the reign of Egbert, who united it with the other Saxon states under one government. Alfred divided the county into seven hundreds, exclusive of Chester, which is a county in itself. Canute the Dane, who obtained this division of the kingdom by his famous partition treaty with Edmund Ironside, invested the administration of this county in the earls of Chester, three of whom enjoyed that dignity prior to the conquest; Leofric the son of Leofwin; Algar his son; and Edwin son of the latter, in whom ended the race of the Cheshire earls of Saxon blood. On the conquest, the provinces of Britain, which had hitherto been governed by a few great men, were divided into lesser portions, and distributed as rewards among the followers of the Norman king. Cheshire was bestowed on Gherbot, a valiant Fleming, and after him on Hugh de Aurange, better known by the name

---

† In this county there are enumerated 1 city, 12 towns, and 1670 villages.

Cheshire.

of Hugh Lupus. To him the monarch delegated a fulness of power, made this a county palatine, and gave it such a sovereign jurisdiction, that the ancient earls kept their own parliaments, and had their own courts of law, in which any offence against the dignity of the sword of Chester, was as cognizable as the like offence would have been at Westminster against the dignity of the royal crown; for William allowed Lupus to hold this county *tam libere ad gladium, sicut ipse rex tenebat Angliam ad coronam.* The sword with which he was invested for this purpose, is still to be seen in the British Museum, inscribed, *Hugo comes Cestriæ.* As soon as Lupus was firmly established, he began to exert his regal prerogatives, forming his parliament by the creation of 8 barons, who were obliged to pay him attendance, and, with a view to giving it greater dignity, to repair to his court. They were bound, in all wars between this county and Wales, to find, for every knight's fee, a horse with caparison and furniture, or two without furniture, for the division of Cheshire. Their knights and freeholders were to have corselets and habergeons, and were to defend their lands with their own bodies. Every baron had also four esquires, every esquire one gentleman, and every gentleman one valet. Each of these barons had moreover his free court of all pleas and suits, and all plaints, except what belonged to the earl's sword. They had even the power of life and death; the last instance of the exertion of which was in the person of Hugh Stringer, who was tried for murder in the baron of Kinderton's court, and executed in 1597. This species of government continued from the conquest till the reign of Henry III., a period of 171 years, when in 1237, on the death of John Scot, the seventh earl of the Norman line without male issue, Henry took the earldom into his own hands, and gave the daughters of the late earl other lands in room of them, being unwilling, as he said, that so great an inheritance should be parcelled out among distaffs. The king bestowed the county on his own son Edward, who did not assume the title, but afterwards conferred it on his son Edward of Caernarvon. Since that time, the eldest sons of the kings of England have always been earls of Chester, as well as princes of Wales. The palatinate was governed by the earls of Chester as fully and independently, for nearly three centuries after this period, as it had ever been by the Norman earls; but Henry VIII., by authority of parliament, made it subordinate to the crown of England. Yet notwithstanding this restraint, all pleas of lands and tenements, and all contracts within the county, are to be heard and determined in it; and all determinations out of it are deemed void, *et coram non judice*, except in case of error, foreign plea, and foreign voucher; and for no crime but treason can an inhabitant of this county be compelled to be tried out of it. Thus being solely under the jurisdiction of its own earls, and considered in a certain degree as a separate kingdom, representatives to the national parliament were never sent, either for the shire or city, till the year 1549, the third of Edward VI., when, upon the petition of the inhabitants, two members were summoned from each. This practice has accordingly been continued, and Cheshire returns four members to parliament, viz. two for the shire, and two for the city of Chester. It pays 7 parts of the land tax, and furnishes the militia with 560 men. Within the diocese of Chester are comprehended not only all Cheshire and Lancashire, but various parts also of Westmoreland, Cumberland, Yorkshire, Denbighshire, and Flintshire. This diocese is divided into two archdeaconries.

Cheshire contains various curiosities in the departments both of nature and of art. In the library of Vale Royal Abbey, the residence of an ancient family, situated near the centre of the county, there is preserved a very choice rarity, viz. a collection of writings called the Prophecies of Nixon, the famous Cheshire prophet, with respect to whom a pamphlet was published some time ago at Chester, purporting to contain his original predictions, and giving some account of his life. In the register of the church of Frodsham, there occur two remarkable instances of longevity: On March 13th 1592, Thomas Hough was buried at the great age of 141; and, on the succeeding day, Randle Wall aged 103. What is more deserving of notice, is a singular instance that is on record of the versatility of nature, as displayed in the person of a native of this county named Mary Davis, who was born at Great Aughall near Chester, about the year 1598. At the age of 28, a wen-like excrescence appeared above her ear on the right side of the head, and after 32 years continuance grew into 2 horns, which remained for 5 years, and were then shed. These were succeeded by 2 new ones, which, about 4 years from their first appearance, were also cast, and their places occupied by two others. Several portraits were made of this woman when upwards of 70 years of age, one of which is now in the British, and another in the Ashmolean museum. In the latter collection one of her horns is preserved. In 1679, when more than 80 years old, she was exhibited in London.

The following statistical abstract for Cheshire is taken from the recent population return for 1811.

Number of inhabited houses	41,187
Number of families that occupy them	44,502
Houses building	250
Uninhabited houses	1259
Families employed in agriculture	16,396
——————— trade, manufactures, &c. .	23,043
Families not included in these classes	5,063
Number of males	110.841
Number of females	116,190
Total population	227,031
Ditto, including a proportion for those employed in the navy and army	234,600
Increase since 1801	36,500

Chess.

CHESS, an ingenious and very ancient game of skill, played on a board divided into squares or houses, generally 64 in number, with a variety of men or pieces differing from each other in form and in name.

It is generally played in Europe with 16 pieces of a side, painted or stained for distinction's sake, of two different colours, as white and black. Of these 16 pieces, eight are dignified, viz. a king, a queen, two bishops, two knights, and two rooks; and there are eight of lower dignity and equal rank called pawns. They are placed opposite to each other in two lines, at the edges of the board of 64 chequers, in the following order. The white king is to be placed on the fourth black house or square from the corner, on the first or lower line; and the black king opposite to him on the fourth white house, at the adversary's side of the board. The queens are to be placed next the kings, on houses of their own colour. Next to the king and queen, on each hand, the bishops are to be placed; next to them the two knights; and last of all, at the corners of the board, the two rooks.

The pawns are to be placed without distinction, on the second line, or rank, one before each of the dignified pieces.

The moves of the pieces are as follows: The pawns move straight forwards in their own files, one house at a time; but when first played, may be carried forward two houses at a time, if the player chooses. They never move backwards, sidewise, or diagonally, unless in taking an enemy's piece, which is done one diagonal move in advance, the pawn occupying the house of the captured piece—a rule which applies to every case of capture. The rook moves straight forwards, backwards, and sidewise, or by rank or file at pleasure, the whole compass of the board. The bishop moves diagonally, always keeping the same colour, over the whole board, forwards or backwards. The queen combines the moves of the rook and bishop, which renders her a very important piece. The king does the same, only he is circumscribed to passing over one house at a time. The motion of the knight is the most irregular, being a kind of vault over the adjacent square into that which is next to it sidewise, and of a different colour. The range, therefore, of his move, is limited, but it may be either forwards, backwards, or sidewise. The game is not won, in consequence of having taken the pieces of the adversary, but by placing his king in such a situation that he is exposed to be taken, or is *in check*, and cannot move into any other situation without being also *in check*, or exposed to be taken, which is called *checkmate*.

Such is the mode of playing the game in Europe; but in the East, where it is in very great vogue, it is often found in a different form. Frequently the queen has the move of the knight, as well as of the rook and bishop; and sometimes there are additional pieces used, by which the game is rendered much more complicated.

Sir William Jones, in the second volume of the *Asiatic Researches*, describes a very complicated kind of chess, from one of the Sanscrit books called *Puranas*, which has the name of *Chaturaji*, or the game of four kings: being played by four persons representing as many princes, two allied armies combating on each side. It is thus described in the *Bhawishya* Puran, the book alluded to. " Eight squares being marked on all sides, the red army is to be placed to the east, the green to the south, the yellow to the west, and the black to the north. Let the elephant (says the Puran) stand on the left of the king, next to him the horse, then the boat, and before them all four foot soldiers; but the boat must be placed in the angle of the board." Particular rules are subjoined for the conduct of the game; and some of the moves are directed by throwing the dice, in which it differs materially from chess as most commonly played. We refer to the *Asiatic Researches* for what the president has said farther concerning this curious game; subjoining only the following remark: " A ship or boat is absurdly substituted, we see, in this complex game for the *rat'h*, or armed chariot, which the Bengalese pronounced *rot'h*, and which the Persians changed into *rokh*; whence came the *rook* of some European nations; as the *vierge* and *fol* of the French are supposed to be corruptions of *ferze* and *fil*, the *prime minister* and *elephant* of the Persians and Arabs."

In a letter from Eyles Irwin, Esq. to the Earl of Charlemont, in 1793, published in the fifth volume of the *Irish Transactions*, there is an interesting account of the Chinese mode of playing the game of chess. " A young mandarine," says Mr Irwin, " of the profession of arms, having an inquisitive turn, was my frequent visitor; and what no questions could have drawn from him, the accidental sight of an English chess-board effected. He told me that the Chinese had a game of the same nature; and on his specifying a difference in the pieces and board, I perceived, with joy, that I had discovered the desideratum of which I had been so long in search. The very next day my mandarin brought me the board and equipage; and I found that the Bramins were neither mistaken touching the board, which has a river in the middle to divide the contending parties, nor in the powers of the king, who is intrenched in a fort, and moves only in that space, in every direction. But what I did not before hear, nor do I believe is known out of this country, there are two pieces, whose movements are distinct from any in the Indian or European game. The mandarin, which answers to our bishop, in his station and sidelong course, cannot, through age, cross the river; and a rocket boy, still used in the Indian armies, who is stationed between the lines of each party, acts literally with the motion of the rocket, by vaulting over a man, and taking his adversary at the other end of the board. Except that the king has his two sons to support him, instead of a queen, the game, in other respects, is like ours, as will appear in the plan of the board and pieces I have the honour to enclose, together with directions to place the men and play the game."

The Chinese call this game *Chong Kè*, or the royal game; and the following is the mode of playing it, according to Mr Irwin: " As there are nine pieces, instead of eight, to occupy the rear rank, they stand on the lines between, and not within the squares. The game is consequently played on the lines. The king, or *chong*, stands in the middle line of this row. His moves resemble those of our king, but are confined to the fortress marked out for him. The two princes, or *sons*, stand on each side of him, and have equal powers and limits. The mandarins, or *tichong*, answer to our bishops, and have the same moves, except that they cannot cross the water, or white space in the middle of the board, to annoy the enemy, but stand on the defensive. The knights, or rather horses, called *māā*, stand and move like ours in every respect. The war-chariots, or *tehé*, resembled our rooks or castles. The rocket-boys, or *paö*, are pieces whose motions and powers were unknown to us. They act with the direction of a rocket, and can take none of their adversary's men that have not a piece or pawn intervening. To defend your men from this attack, it is necessary to open the line between, either to take off the check or the king, or to save a man from being captured by the *paö*. Their operation is otherwise like that of the rook. Their stations are marked between the pieces and pawns. The five pawns, or *ping*, make up the number of the men equal to that of our board. Instead of taking like ours, they have the rook's motion, except that it is limited to one step, and is not retrograde. Another important point in which the *ping* differs from ours, is, that they continue in *statu quo*, after reaching their adversary's head quarters. It will appear, however, that the Chinese pieces far exceed the proportion of ours, which occasions the whole force of the contest to fall on them, and thereby precludes the beauty and variety of our game, when reduced to a struggle between the pawns, who are capable of the highest promotion, and often change the fortune of the day. The posts of the *ping* are marked in front."

Mr Twiss mentions a small treatise on chess, written, as he supposes, about 400 years ago, at the end of which is a representation of a round chess-board, with directions for placing the men upon it. The board is divided into 64 compartments by four concentric circles, each divided into 16 parts, an empty space being left in the middle. Number 1 is marked or placed in the outermost circle; number 2 in the third circle, counting inwards in the division to the right hand of the former; number 3 is placed in the outermost circle, in the division to the right hand of 2; 4 in the third circle, counting inwards to the right hand of 3; and others alternately from the first to the third, and from the third to the first circle, till the round is completed by 16 on the third circle to the left hand of 1. Number 17 is then placed on the division of the innermost circle to the right hand of 1; 18 on the second circle, counting inwards to the right hand of 17; and thus alternately from the fourth to the second, and from the second to the fourth circles, until the round is completed by 32 directly below number 1. Number 33 then is placed on the third circle, directly to the right hand of number 2; 34 on the fourth circle, directly below number 33. The numbers are now placed in a retrograde fashion; 50 on the outer circle, in that division immediately to the right hand of 1; 51 on the third circle, to the left hand of 2, and directly below number 32; 52 is then placed on the outer circle, immediately on the left hand of 16; and thus alternately on the first and third circles, until the last ground is completed by 64 between the numbers 3 and 5.

On this round chess-board, supposing the black king to be placed in number 48 on the fourth circle, the queen stands on number 17 at his left hand; the bishops in 33 and 2; the knights 18 and 47; the castles 3 and 50; the pawns on 19, 4, 49, 64, and 46, 51, 32, 1. The white king will then stand in 25 opposite to the black queen; the white queen in 40, opposite to the black king, and so forth. In playing on a board of this kind, it will be found that the power of the castle is double to that in the common game, and that of the bishop only one half; the former having 16 squares to range in, and the latter only four. The king can castle only one way; and it is very difficult to bring the game to a conclusion.

The Russians are said to be great proficients at chess; and with them the queen has, in addition to her other moves, that of the knight also; which, according to Philidor, spoils the game, but renders it much more complicated. The Russians play also at chess with four persons at the same time, two against two; for which purpose the board is longer than usual, contains more men, and is provided with a greater number of squares.

In Thibet and the Birman empire, as indeed throughout all the East, this game is held in high estimation. The board used by the Birmans, as we learn from Symes's Embassy to Ava, (vol. iii. p. 289.) is exactly similar to ours, containing 64 squares, and the number of their troops the same, 16 on each side; but the names, the power, and the disposal of them differ essentially. The king and his minister (corresponding to our queen) are mounted on elephants; these are defended by two castles, two knights on horseback, two officers on foot, and eight foot soldiers; the forces of each party are arranged in three lines, by which eight squares remain unoccupied; none of the pieces possess equal force with our queen; by which restricted operation, according to Mr Symes, the Birman mode of playing is rendered more complex and difficult than ours. The game is known in that country by the name of *chedreen*, which bears some resemblance to the appellation by which it is distinguished in most other parts of the world.

It appears likewise from Lord Valentia's late travels in the East, that the game of chess is a favourite amusement with the Abyssinians. "In the evening," says Mr Salt, (who was sent by his lordship into Abyssinia,) "we went into the hall, and found the Ras at chess in the midst of his chiefs. The chess men, which are coarsely made of ivory, are very large and clumsy. When they have occasion to take any one of their adversary's pieces, they strike it with great force and eagerness from its place. I observed that their game differs much from ours. Bishops jump over the heads of knights, and are only allowed to move three squares. The pawns move only one step forward at starting, and get no rank by reaching the end of the board. They play with much noise, every person around, even the slaves, having a voice in the game, and seizing the pieces at pleasure, to shew any advisable move. We observed, however, that they always managed with great ingenuity to let the Ras win every game.

The game of chess is allowed upon all hands to be of very great antiquity; but concerning its origin, as well as the etymology of the name by which it is so generally denoted, a great variety of opinions have prevailed. It has been maintained by many learned writers, that the invention of this game was due to Palamedes at the siege of Troy. The various passages of the ancients, which have been relied on in proof of this opinion, may be seen in Stephen's *Thesaurus*, under the word πεσσος, a *pebble*. One of the principal is the following line of Sophocles:

Εφευρε (sc. Palamedes.) πεσσοις κυβοις τε τερπνον αργιας ἀκος.

But from this nothing more can be inferred, than that Palamedes invented some game which was played with pebbles. From a line in the first book of the *Odyssey*, it has been inferred, that Penelope's suitors amused themselves with this game before the gates of Ulysses's palace. The game played by Penelope's suitors, and called πεττεια, is particularly described by Athenæus, on the authority of a native of Ithaca; (*Deipnosoph.* l. 1.) and it differs very materially from chess, the number of the pieces being 108 instead of 32. The game called πεττεια in Greek, was by the Romans termed *calculi*, or *latrunculi*; and Ovid (*Art. Am.* l. 3.) has so described the manner of playing it, that no person who is in the least acquainted with chess, can conceive that it alludes to this game.

It seems probable, that chess was introduced into Europe by the crusaders in the 11th or 12th century, at which period it was a game in very common use both among the Greeks and Saracens. The Princess Anna Comnena, in the life of her father Alexis Comnenus, who was emperor of the Greeks in the 11th century, informs us that the game of chess, which she calls ζατρικιον, came from Persia into Greece; so that it is in the East that we are to look for its origin. The Persians themselves lay no claim to this invention, but unanimously agree, that they received the game from the Indians at the beginning of the 6th century, during the reign of Chosroës the Great. "The Persians," says Sir William Jones, "though as much inclined as other nations to appropriate the ingenious inventions of a foreign people, unanimously agree, that the game (of chess) was imported from the west of India, together with the charming fables of *Vishnasarman*, in the sixth century of our era." (*Asiatic Researches*, vol. ii.)

This profound orientalist coincides with the learned Hyde, and is decidedly of opinion, that chess was invented in Hindustan, where, he says, it has been immemorially known by the name of *Chaturanga*, that is, the four *angas*, or members of an army, viz. elephants, horses, chariots, and foot soldiers; and, in this sense, the word is frequently used by epic poets in their descriptions of real armies. The Arabic writers have likewise ascribed the honour of this invention to the Indians, and have delivered the following interesting and well-known tradition concerning its origin.

At the beginning of the 5th century of the Christian era, there reigned over the Indies a young monarch of an excellent disposition; but who being corrupted by the flatteries of his courtiers, became the tyrant and oppressor of the lower orders. The *brahmins* and the *royals*, that is to say the priests and the nobles, in vain endeavoured to repress his severities; when a learned brahmin named *Sissa*, undertook indirectly to open his eyes. With this view he invented the game of chess, in which the king, though the most important of all the pieces, is unfit for an attack, or even for self-defence, without the aid of his subjects. The tradition adds, that the scheme was successful. The king became convinced of his error; and, desirous of rewarding his venerable instructor, requested him to name his own recompense. The demand of the brahmin was apparently moderate. He asked only a single grain of corn for the first chequer of the chess-board, two for the second, four for the third, eight for the fourth; and so on in a continually doubling proportion for the whole 64 chequers. The king readily agreed to what appeared so reasonable; but when his treasurers proceeded to calculate the amount, they discovered to their astonishment, that the whole dominions of the monarch were insufficient to discharge the debt. They found, in fact, that such a quantity of corn would be equivalent to 16,384 cities, each of which should contain 1024 granaries, in each of which there should be 174,762 measures, containing each of them 32,768 grains. Upon this the brahmin again took occasion to exhort his majesty how liable he was to be deceived by those who surrounded him; and how necessary it was to take care that a bad use should not be made even of his best intentions.

Certain authors, however, have been more disposed to ascribe the honour of the invention of chess to the Chinese than to the Hindus. Such is the opinion of the honourable Daines Barrington, in his elaborate "Historical disquisition on the game of Chess." (*Archæol.* vol. ix.) Such also is the opinion of Mr Irwin, in the paper already quoted. The young mandarin, named Tingica, who shewed him the Chinese chess-board, claimed this honour for his countrymen, and brought him a Chinese MS. containing an account of the origin of the game. It was an extract from the *Concum*, or Chinese annals, and is as follows:

"379 years after the time of Confucius, or 1965 years ago, Hung Cochu, king of Kiangnan, sent an expedition into the Shensi country, under the command of a mandarin called Hansing, to conquer it. After one successful campaign the soldiers were put into winter quarters, where finding the weather much colder than what they had been accustomed to, and being also deprived of their wives and families, the army, in general, became impatient of their situation, and clamorous to return home. Hansing upon this revolved in his mind the bad consequences of complying with their wishes. The necessity of soothing his troops, and reconciling them to their position, appeared urgent, in order to finish his operations in the ensuing year. He was a man of genius, as well as a good soldier; and having contemplated some time on the subject, he invented the game of chess, as well for an amusement to his men in their vacant hours, as to inflame their military ardour, the game being wholly founded on the principles of war. The stratagem succeeded to his wish; the soldiery were delighted with the game; and forgot, in their daily contests for victory, the inconveniences of their post. In the spring the general took the field again, and, in a few months, added the rich country of Shensi to the kingdom of Kiangnan, by the defeat and capture of its king Choupayuen, a famous warrior among the Chinese. On this conquest Hung Cochu assumed the title of emperor, and Choupayuen put an end to his own life in despair."

Du Halde, however, and the other Chinese missionaries, are not disposed to ascribe the origin of chess to China; and say expressly, that the Chinese themselves acknowledge that they received the game from the Hindus. Mr Freret, in a memoir on the subject in the Transactions of the Academy of Belles Letters, asserts that it is said in the *Haï-Pien*, or great Chinese dictionary, that this game was introduced from India into China under the reign of *Vouti*, about the year 537 before Christ. The claim of the Hindus, therefore, to the honour of this invention, seems on the whole the best supported.

With respect to the origin of the name by which it has been commonly distinguished, Sir William Jones is disposed to derive it from the Sanscrit appellation of *chaturanga*, or the game of the four *angas*, or members of an army. "By a natural corruption of the pure Sanscrit word," says he, "it was changed by the old Persians into *chatrang*; but the Arabs, who soon after took possession of their country, had neither the initial nor final letter of that word in their alphabet, and consequently altered it further into *shatrang*, which found its way presently into the modern Persian, and at length into the dialects of India, where the true derivation of the name is known only to the learned. Thus," adds he, "has a very significant word in the sacred language of the Brahmans, been transformed by successive changes into *axedrez*, *scacchi*, *echecs*, *chess*; and, by a whimsical concurrence of circumstances, given birth to the English word *check*; and even a name to the *exchequer* of Great Britain."

The authority of so great an etymologist must be received with the highest respect; nevertheless it appears almost certain, that the name by which this game was most familiarly known over the East did not import the *game of the four angas*, but the *game of the king*, an honour not unjustly due to the dignity of this most important of all the pieces. Sir William Jones himself states in the same memoir, that the species of chess played in India with four different colours of men, which we have already noticed, though also called *chaturanga*, is more frequently called *chaturaji*, or the *four kings*. Mr Irwin informs us, that the Chinese name for chess is *chong kê*, or the *royal game*; and it was known in Persia under the appellation of *schatrak*, meaning the game of the *schach* or king, and bearing a close resemblance to the *chaturanga* of India. From Persia, chess was introduced among the Constantinopolitan Greeks, and called *ζατρικιον*; whence the *axedres* and *al xadres* of the Spaniards and Saracens. The same term has evidently given rise to the *scaccorum ludus* of the Latins, the *scacchi* of the Italians, the *echecs* of the French, and, finally, the *chess* of the English.

This etymology, which is that of Bochart, is at least more plausible than that of Leunclavius, who derives the name from *Uscoches*, famous Turkish robbers; or of P. Lermond, from the German *scache*, "theft"; or of G. Tolosanus, from the Hebrew *scarch*, "vallavit." It also explains the force of the term *check*, which is employed in the game when the king is in danger from any piece, and which was nothing else originally than the title of the king himself; and it accounts for the origin of the decisive stroke of the game *check-mate*, which is compounded of *schach*, "the king," and *mat*, a word expressing "dead" in Persian and other Eastern languages.

The *schach* or king has retained his name and dignity throughout every variation of the game of chess. The next piece in dignity, however, which has long been called the queen in Europe, was never so denominated in the East; but had the rank of minister, or visir, or *ferz*, among the Persians; a name which it has been supposed, with great probability, was corrupted into *vierge* by the French; whence the origin of a female upon the chess-board. The old French poets, such as the author of the *Roman de la Rose*, call this piece *fierce*, *fierche*, and *fierge*; and, in a manuscript of Lydgate, monk of St Edmund's Bury, quoted by Dr Hyde, the fate of the king in a game of chess is thus described:

> "Was of a *fers* so fortunate,
> Into a corner drive and maat."

The rook or rok has his name, according to Sir William Jones, from the Bengalese *rot'h*, or Persian *rok'h*, signifying an armed chariot; and such, we have seen, is the designation of this piece among the Chinese, according to Mr Irwin. Others deduce it from the Indian name of a *camel*, by which the chariot was drawn; and if we suppose the chariot fitted up like the castle which is fixed on the elephant's back, when he is equipped for battle, we get a plausible origin of the term *castle*, as well as of the form now commonly given to this piece. The *knights*, or *horses* as they are frequently called, have continued unchanged in all the variations of the game; but the same has not been the fate of the piece which we now strangely enough call a bishop. Among the Chinese he was a mandarin; among the Indians an *elephant*, called in that language *fil*, whence seems to have come the *fol* or *fool* of the French. By old English writers, this piece is called *alphin ausin*, or *elphyn*, from an Arabic word signifying an elephant; and he still is called an elephant by the Russians and Swedes. Sometimes he has been an archer; and, among the Germans, he is a *hound* or *runner*. The Poles call him the *priest*, and the English the *bishop*; for what reason it is not easy to say; possibly from an accidental conversion of the cap and bells of the French *fol*, into the bifurcated mitre of a bishop. The pawns are supposed to receive their name from *pedones*, a barbarous Latin term for foot soldiers; but it is more probable that the word comes from an Eastern term of the same import. In China, we have seen that they are called *ping*, which is almost identical with the French *pion*. The Germans, Danes, and Swedes, have converted these subordinate pieces into peasants.

It would be impossible, in a work like ours, to give any thing like a treatise on this interesting game; and we must therefore refer our readers to the work of Philidor; and to an *Introduction to the Game of Chess*, London, 1809, a work which contains an excellent selection of games.

As it is often necessary, however, to refer to the laws of chess, the powers of the pieces, the possibility of winning, and the conclusions of games, we subjoin the following from the above-mentioned work:

Laws of Chess.

1. If you touch a piece or pawn you must play it; but if it is displaced, or overturned by accident, you are allowed to restore it to its place.

2. After quitting hold of a piece or pawn, you cannot take it again to play it to another place; but so long as you keep hold of it, you are at liberty to play it where you please.

3. If you touch one of your adversary's pieces or pawns, he has a right to oblige you to take it, if in your power; if not, to move your king, if you can without putting it upon check.

4. If by mistake, or otherwise, you make a false move, your adversary may insist on your moving your king (as in Art. 3.); but if he takes no notice of it until he has played his next move, neither of you can recal it; the position must remain as if it had been just.

5. If you touch a piece or pawn, which you cannot play without exposing your king to *check*, you must then move your king; which if you cannot do, the fault is of no consequence.

6. If your adversary gives *check* without warning, you are not bound to ward it off, and may consequently play as if such check did not exist; but if on his next move he warns you, each must then retract his last move, as being false, and you must remove your king off check.

7. If your adversary warn you of a check, without however giving it, and you in consequence touch or move either your king or any other piece or pawn, you are allowed to retract, provided your adversary has not completed his next move.

8. You cannot give check to your adversary's king with a piece, which, by your so doing, would discover check on your own king.

9. If you attempt to castle your king when you have no right,—that is, after it, or the rook with which you purpose castling it, has moved,—your adversary may insist on your moving either your king or that rook.

10. After the first game, the players have the first move alternately. If the advantage of a piece or pawn is given, the player giving such advantage is entitled to the first move.

The Value and Power of the Pieces.

King, ...	$6\frac{1}{2}$
Queen, ...	$23\frac{3}{4}$
Rook, ...	15
Bishop, ...	$9\frac{3}{4}$
Knight, ...	$9\frac{1}{4}$
Pawn, power of, . . .	2
——— value of, ...	$3\frac{3}{4}$

From the very principle of the game, the king is invaluable; but its power for attack and defence may be estimated as above.

From the chance which every pawn has of being converted into a more valuable piece, when it reaches the adversary's royal line, its value is estimated at $3\frac{3}{4}$, though its power is only 2.

Conclusions of Games.

1. A single pawn cannot win if the adverse king be placed in opposition to it.

2. A single pawn may win, if the king be placed before its pawn.

3. Two pawns against one must win, almost in all cases; but the player that has the two pawns must avoid changing one of them for his adversary's pawn.

4. A pawn and any other piece must win in all cases; except a pawn and a bishop, when the pawn is on a rook's file, and the bishop does not command the square on which the pawn will reach the royal line.

5. Two knights, without any other piece or pawn, cannot give check-mate.

6. Two bishops may win.

7. A knight and a bishop may win.

8. A rook against a knight makes a drawn game.

9. A rook against a bishop makes a drawn game.

10. A rook and a knight against a rook makes a drawn game.

11. A rook and a bishop against a rook may win.

12. A rook and a bishop against a queen makes a drawn game.

13. A rook and a knight against a queen makes drawn game.

14. A queen against a bishop and a knight may win.

15. A queen against a rook and two pawns makes a drawn game.

16. A rook against a bishop and two pawns makes drawn game.

17. A rook against a knight and two pawns makes a drawn game.

18. At all conclusions of games, when a player seems not to know how to give the difficult check-mates, (as that of a knight and bishop against a king, a rook and a bishop against a rook, &c.) fifty moves on each side must be appointed for the end of the game: these being accomplished, it is to be reckoned a drawn game.

The following short precepts, which have been drawn up as a sort of manual by an experienced chess-player, will be found of great advantage even to an experienced player:

Reflections to be made at Chess before moving any Piece.

Consider, 1. Whether your piece will be defended by another in its new position; and still better, if defended by two or more.

2. Whether the adversary can immediately make an attack upon it; and if by a piece of inferior value, the move is certainly a bad one, unless it be merely preparatory to another move.

3. Consider carefully whether you place your piece, so as to be either on the direct or oblique line with another piece behind it, and open to attack; which is generally a bad position, because your adversary's rook, queen, or bishop may then check both your pieces. This observation, however, does not apply to the case, where your two pieces guard each other; but it applies with peculiar force to the case of the king, and any other piece at a distance from him, on account of the necessity of immediately removing the king from check.

4. Consider well when you attack an enemy's piece, whether you do not force it into a position more disadvantageous to yourself than that in which it was before.

5. If possible, never move a piece till you have discovered your adversary's intention in his last move. If you are unable to do this, try to drive back the piece he has last moved.

6. Consider before moving, whether your adversary can check your king; and if so, how the check can be removed, because the necessity of immediately doing this may occasion you a loss, if you do not keep it always in view.

7. Be particularly on your guard, when the game is in such a situation, that you are exposed to a *check by discovery*, either by the adversary's moving a piece of his own, or driving away one of yours; for an oversight in such a situation will probably cost you the game.

8. When the adversary is intent on bringing up a piece to the attack, prevent him if you can, by placing a pawn, or other piece, so that his piece cannot be moved farther, without being exposed to capture.

9. Never move till you have explored every part of the board, and the situation of every piece; for oversight is the greatest danger you have to dread.

The game of chess, being a miniature representation of a battle, has been a favourite amusement in all ages, with the greatest warriors and generals. The celebrated Tamerlane was a great chess-player, and made use of a board of a peculiar construction, having eleven squares in breadth, and twelve in height, so as to form altogether 132 houses. We read that he was engaged at chess during the decisive battle with Bajazet, in which that emperor was defeated and taken prisoner; and at another time he was engaged at the same game, and in the very act of giving check-mate with a rook, when he was informed, that a son had just been born to him; upon which, to commemorate so remarkable a circumstance, he resolved that his son should have the name of Schachrochk, or *check by the rook*. Dr Hyde quotes an Arabic history of the Saracens, in which it is said, that when Al Mamon's forces were carrying on the siege of Bagdad with so much vigour, that it was on the point of being taken by assault, the besieged caliph, Al Amin, was engaged at chess with his freedman Kuthar. Being warned of his danger, he exclaimed, "Let me alone, for I see check-mate against Kuthar!" Modern history affords similar examples of the power of this game in engrossing the whole soul. John Frederic, Elector of Saxony, having been taken prisoner by the Emperor Charles V., was condemned to death. The decree was intimated to him while he was engaged at chess with Ernest of Brunswick, his fellow prisoner. After a short pause, and making some reflections on the irregularity and injustice of the emperor's proceedings, he turned to his antagonist, whom he challenged to finish the game. He played with his usual ingenuity and attention; and having beat Ernest, expressed all the satisfaction that is commonly felt on gaining such victories. He was not, however, put to death, but set at liberty after five years confinement. We are told, that Charles I. of England was at chess, when news were brought of the resolution of the Scots to sell him to the English; but so little was he disturbed by this alarming intelligence, that he continued his game with the utmost composure; so that no one could have discovered that he had received information of any thing remarkable.

In the Chronicle of the Moorish Kings of Granada, it is related, that, in 1396, Mehemed Balba, who had seized the crown in prejudice of his elder brother Juzaf, after a series of disasters, was killed by means of a poisoned vest. Finding his end at hand, he dispatched an officer to the prison of his brother, with orders to put him to death, lest his adherents should form any obstacle to the accession of his own son. The officer found the prince playing at chess with an *alsaqui*, or priest. Juzaf begged hard for two hours respite, which was denied him. At last, with great reluctance, the officer permitted him to finish the game; but before it was closed, a messenger arrived with the news of the death of Mehemed, and the unanimous election of Juzaf to the crown.

The game of Chess seems to have been known at a very early period in France, of which we have evidence in an account, given by Carte the historian, of a chess-match between Henry I., before his accession to the throne of England, and Louis le Gros, son to Philip of France, which took place at Philip's court in 1087. Louis lost several games to Henry, and a considerable sum of money, by which he was so much irritated, that he threw the chess-men at Henry's head. Henry retaliated the affront, by striking Louis with the board, so that he was laid bleeding on the floor; and Henry would have killed his antagonist, if his elder brother Robert had not interposed. John of Salisbury relates of the same Louis le Gros, in his book *De nugis curialium;* that, in a battle between the French and English in 1117, an English knight seizing the bridle of the French monarch, and crying out to his comrades, "the king is taken!" Louis struck him to the ground with his sword, saying, "*Ne scais tu pas qu' aux echecs, on ne prend pas le roy?*"

There have been various attempts, among modern chess-players, to improve, or at least to vary the game, which have, however, generally died with their inventors. Pietro Carrera, who wrote upon chess in 1617, invented two new pieces, one of which, called *campione*, was placed between the king's knight and castle, and had the move of both these pieces: the other, named *centaur*, was placed between the queen's knight and castle, and had the move of the bishop and knight united. Francisco Piacenza, who styles himself a doctor of laws, proposed another plan of two additional pieces, called a *centurion* and *deacrion*, in 1683. The former, situated between the king and his bishop, unites the move of the knight with that of the queen and castle, for any two squares only: the latter, situated between the queen and her bishop, has the move of the bishop; but only for one square at a time. A still more complicated game of chess was invented by the late Duke of Rutland, of which Sir Abraham Janssen, an excellent chess-player, was extremely fond. The chess-board was 14 squares in breadth, and 10 in height; and the pawns, of which there were 14 on a side, may move either one, two, or three squares the first time. The other pieces were the king, queen, two bishops, two knights, a crowned castle, uniting the move of the king and castle, and a common castle. On the other side of the king was a concubine, whose move united that of the castle and knight, two bishops, a single knight, a crowned castle, and a common one. In this game, the pawns and knights lose much of their value, on account of the extent of the board.

Several other varieties of the game are specified, in which the advantage given by one player to the other, consists in allowing him *il Rè-cavallo*, or *la Donno-cavallo;* that is, that his king or queen may likewise move like the knight. But in the opinion of adepts, the simple form of the game is the best; and is sufficiently complicated to call forth all the ingenuity of the players. One amusing variety, however, still deserves to be mentioned, in which the king, with eight pawns, engages the whole set, on condition of being allowed two moves for every one of his adversary. In this case he can make his first move into check, and his second out of it, by which he has a great advantage; and he cannot be check-mated unless his adversary has preserved his queen and both castles.

The annals of chess record some extraordinary performances of certain adepts at this game, who were accustomed formerly to make a livelihood of their art. Such as Paolo Boi, commonly called the Syracusan, who played at chess with Sebastian, king of Portugal; and at the court of Philip II. of Spain; and his cotemporary Leonardo of Cutri, known by the appellation of *il Puttino*, or the boy. The fame of all these, however, seems to have been exceeded by that of Mr Philidor, whose exhibitions have been made in the presence of many persons still living. This extraordinary chess-player was bred a musician, in the band of the French king; a situation which his father and grandfather had enjoyed before him. At six years of age he was admitted among the children of the chapel royal of Versailles, where, being obliged to attend daily, he had an opportunity of learning chess from the musicians in waiting, of whom there were about eighty. Cards not being allowed so near the chapel, they had a long table with six chess-boards inlaid. Young Philidor soon became greatly attached to the game; and having obtained instructions from Mr de Legalle, who was esteemed the best chess-player in France, he thought of trying to play by memory, having found that he was able to calculate moves, and even whole games at night, while he was lying in bed.

He soon after this offered to play two games at the same time, at a coffee-house in Paris, without seeing either board; and succeeded so well, that he beat two antagonists, to either of whom he, though a first rate player, could only give the advantage of a knight when seeing the board. In the middle of one of the games, a false move was purposely made to try his skill, which, after a great number of moves he discovered, and placed the piece where it ought to have been at first.

Forty years after this he played two different times in London, three games at once. Of one of these exertions, the following account appeared in the London newspapers in May 1783: "Yesterday, at the chess club in St James's street, Mr Philidor performed one of those wonderful exhibitions for which he is so much celebrated. He played, at the same time, three different games, without seeing either of the tables. His opponents were, Count Bruhl, Mr Bowdler, (the two best players in London,) and Mr Maseres. He defeated Count Bruhl in an hour and twenty minutes. Mr Bowdler reduced his game to a drawn battle in an hour and three quarters. To those who understand chess, this exertion of Mr Philidor's abilities must appear one of the greatest of which the human memory is susceptible. He goes through it with astonishing accuracy; and often corrects mistakes in those who have the board before them. Mr Philidor sits with his back to the tables, and some gentleman present, who takes his part, informs him of the move of his antagonist, and then, by his direction, plays his pieces as he dictates."

In 1747, Mr Philidor played a match of ten games with *Stamma*, a celebrated chess-player from Aleppo, giving him the move, allowing a drawn game to be a lost one, and betting five to four on each game.* With all these advantages, Stamma won only two games, of which one was a drawn game. Yet it has been asserted, that, towards the close of his life, this wonderful adept at chess, was so beaten by a Turk whom he met with in the suite of an ambassador from the Sublime Porte, that the mortification which he felt from his defeat had the effect of hurrying on his end. (*m*)

CHESTER, an ancient and populous city of England, the capital of Cheshire. It is situated in the hundred of Broxton, at the distance from London of 181 miles, by Coventry and Newport; by Litchfield of 190. It is thus placed near to the southern boundary of the county, where it stands on a rocky eminence above the river Dee, by a sweep of which river it is half encircled. It consists principally of four streets, running from a centre towards the four cardinal points, and each terminated by a gate in the walls, by which the city is surrounded. In respect of the curious structure of these streets, it is called by Mr Pennant a city without a parallel. They are excavated from the rocky soil to the depth of one story beneath the level of the ground, a circumstance which has been the cause of a singular construction also in the houses. On the level of the streets there are low shops or warehouses, and above them is a gallery on each side, which extends from street to street, being open in front, and balustraded. These galleries, called by the inhabitants Rows, are very uncommon and surprising to strangers, who, when walking in them, can hardly divest themselves of the idea, that they are up one pair of stairs. Along the rows are ranges of shops, and above them the higher stories, which project to the streets, forming a line with the shops situated below. The whole appears as if the first stories of all the houses were laid open, and made to communicate with each other, pillars only being left for the support of the superincumbent structure. The principal streets are intersected by various lesser ones, which cross the others at right-angles, so that the inclosed spaces are divided into several smaller squares. The kitchens and back courts of the houses are on a level with the galleries, while carriages drive about eight feet below; and it is necessary for those who would go from their own houses into any of the principal streets, to descend into them by a flight of several steps. Owing to this singular sort of construction, though such as walk on foot are screened from rain, the shops are at the same time rendered dark and inconvenient; and not only they, but the people also who are walking in the rows, are so hid, that one would imagine there were scarcely any inhabitants in it, though really it is very populous. The buildings of the city are in general ancient, but owing to the interspersion among them of some new ones, the whole has rather a motley appearance. Those of the churches that are principally entitled to notice, are the Cathedral, St Oswald's, and St John's; besides which, there are in the city seven other parish churches, which, as buildings however, present nothing particularly deserving of attention. The cathedral is a spacious irregular pile, that is become ragged through the decay of the mouldering stone with which it is built. The lower part of the wall has a row of arches now filled up, and appears to be the oldest part of the present edifice, though none of it indeed can boast of a remote date. All the labours of the Saxons on this spot, and almost all those of the refounder of the building, Hugh Lupus, are now lost. Simon Ripley, elected abbot in 1483, finished the middle aisle of it and the tower, and the initials of his name are interlaid in cyphers on the capitals of some of the pillars. The columns are thick, surrounded by pilasters, with small rounded arches. Above is a gallery, with a neat stone balustrade in the parts where it is entire, and a row of large and broad-pointed windows. With the exception of these slight fragments, most of the present structure seems to have been built in the reign of the three last Henries. The beautiful west end was begun in 1508, when the first stone was laid with much ceremony. The window over the door is filled with elegant tracery, and the door-case enriched with figures and other sculpture. The descent into the church is by several steps, whence it is reasonably inferred, that the present was erected on the foundation of the ancient church, which was originally on a level with the old streets. St Oswald's church forms a part of the Cathedral. St John's stands without the walls on the east side of the city, and is reported to have been founded by King Ethelred in 689, when he had been admonished in a vision to erect it on a spot where he should find a white hind. It was a collegiate church, and, at the dissolution, was possessed by a dean, seven canons, seven vicars, two clerks, four choristers, and various servants. St Peter's church is in the centre of the city, and had formerly a lofty spire steeple. St Bridget's, on the west side of Bridge Street, is neat and convenient, opposite to which is St Michael's, which, of late, has been much enlarged and beautified. Trinity Church, which has undergone similar improvement, stands in Watergate Street: Its handsome spire has been lately taken down. St Mary's, which is situated in the south-west part of the city, has several very handsome monuments. St Olave's stands in the lower part of Bridge Street, opposite to Castle Street; and St Martin's at a place called the Ash: There are also several meeting-houses, public charity-schools, and alms houses. The meeting houses of the Independents and Methodists are modern, and particularly elegant.

Chester Castle, which stands within the walls on the south-west side of the city, seems to have been rebuilt on the Norman model by the conqueror, and enlarged considerably beyond the space it occupied when possessed by the Saxons. It consisted of an upper and lower ward, the entrance to each of which was defended by a gate and round tower. Within the precincts of the upper ballium * are some square towers of Norman architecture, with square projections at the corners slightly salient. The upper room of one of the towers, called Julius Cæsar's, has a vaulted roof, with elegant and slender couples running down the wall, and resting on round pillars, greatly distinguished by their style and beauty of execution. The remaining part of this court is occupied by the arsenal, batteries, and habitable buildings. The noble apartment, called Hugh Lupus's hall, stood on the east side of the lower ward. The roof was supported by wood-work, carved in a bold style, and resting on strong brackets. The length of the room was almost 99 feet, its breadth 45, and its height proportionable. Adjoining to this building was a smaller one, where the chancery court of the county palatine was held, and where the petty sovereigns of the palatinate assembled in council, with their 8 barons. Enough of these old buildings still remains in competent repair in the higher ward, to afford convenient apartments for the accommodation of the judges on the circuit. All the rest of this edifice has been lately taken down to make room for that magnificent structure, the new county gaol, which is not equalled by any similar building in the kingdom. The gaol is built with white freestone, and contains five yards, with a working room and two day-rooms in each, having separate apartments for the women and debtors. The number of solitary cells for condemned criminals is 14. The principal charge incurred in building this splendid fabric was defrayed by the income arising from the river Weaver navigation. The Propylæum, or grand entrance into the castle, is now building: it extends about 100 feet in front, and consists of a centre, and two wings, or pavilions, of the Athenian Doric order. The great entrance is through the intercolumniations; and the whole is of exquisite design and workmanship.

The walls round Chester are in circuit 1 mile 3 quarters and 101 yards. They are the only entire specimens of ancient fortification in Great Britain, but are now preserved only for the purposes of recreation. The continued walk on the top affords a great variety of prospects. The Welsh mountains, the Cheshire hills of Broxton, and the insulated rock of Beeston crowned with its castle, the rich flat interposed, and the perpetually changing views of the river, are the most prominent and striking objects in this favourite tour. The

* The space immediately within the outer walls of the castle.—Grose's *Antiquities*.

expence of the repairs is defrayed by certain imposts called murage-duties, collected at the custom-house on all merchandise brought from beyond sea into the port of Chester. The whole annual amount of these is about £200, great part of which arises from the duty on Irish linens, though the sum levied is only 2d. for 100 yards. These walls were formerly defended by several strong towers, but now only one remains, viz. that called the Phœnix tower, from which Charles I. viewed the defeat of his army at Rowston Moor.

The gates were anciently under the protection of the Earls of Shrewsbury, Oxford, and Derby, and the principal magistrates of the city. The guard was maintained by tolls exacted from strangers at each entrance. These gates are all elegant modern buildings. The Dee bridge is an ancient structure, with seven arches of dissimilar workmanship, no part of which, however, is probably older than the conquest. The city mills stand at the north end of the bridge, and are supplied with water from a current formed by a great dam or causeway, which crosses the river obliquely, and causes a fall of nine feet. These mills with the causeway were founded by Earl Lupus, and the revenues anciently derived from them appear to have been very considerable, as every inhabitant of the city, with the exception of the tenants of the Abbey, was restricted from grinding his corn at any other place. The present extensive premises, which are regarded as extremely complete in their construction, were erected a few years ago, the old mills having been burnt down. The city is chiefly supplied with water from the adjoining works, which raise it from the river into a reservoir, whence it flows through pipes into the houses.

The exchange is a handsome pile, supported partly by columns, and is 126 feet long. It contains, in the south end, a mayor's banqueting-room, which is occasionally used as an assembly room for dancing. In the centre is a spacious hall, in which the courts of sessions, of crownmote, portmote, and annual elections, are held. The north end is occupied by the justices' room, the sheriff's court, the town clerk's office, and other public offices of the city. It was erected in 1698. Near to this building is the engine house, a neat fabric with pilasters, and a rich Corinthian cornice. The fire engines are preserved in order at the expence of the community. In the square opposite the exchange, the market for fish and vegetables is kept. Salmon was formerly sold here in such profusion, that masters were frequently restricted, by a clause in the indentures, from giving it to their apprentices more than twice a week. At a small distance from the exchange are two flesh shambles, which occupy a considerable portion of the street. Here the country butchers are permitted to sell meat on market days. On the top of one of the shambles is a capacious cistern or reservoir, which is supplied with water from the works at the bridge, for the use of the inhabitants of the higher parts of the city.

The infirmary is a handsome structure, pleasantly situated in an airy spot on the west side of the city. Eastward of it is the entrance into the Abbey-court, over the gateway of which is the register-office for wills. The Abbey-court is a pleasant square, and the houses are regular and handsome. Here also is the bishop's palace erected in 1753. The Gothic structure of St Thomas's chapel, the residence of the late Dean Swift, has been taken down, and an elegant mansion erected on the site which it formerly occupied. Of the houses of this city in general, it is to be observed, that many are constructed of timber.

The government of the city of Chester assumed the form of a regular corporation as early as the reign of Henry III. The last charter in its favour was granted in 1676 by Charles II. According to this, the government of the city is vested in a corporation, consisting of a mayor, recorder, 2 sheriffs, 24 aldermen, and 40 common councilmen. Of the latter two are leave lookers, whose office it is to inform of all persons exercising trades within the city without being freemen. The two senior officers are murengers, or receivers of the murage duties for repairing the walls; and two are treasurers, who are usually next in succession to the mayor. There are likewise a sword and a mace-bearer, and various other inferior officers. The exclusive power of election into their own body is assumed by the corporation, though the right of such election was, by the charter of Henry VII., vested in the freemen, citizens who by their own unwise conduct have forfeited the privilege. This city has often been honoured with royal visits, and is remarkable for its perseverance in the cause of royalty when besieged by the parliament army in 1645, at which period the inhabitants of the garrison were exposed in the severest manner to all the calamities of the most distressing famine.

Chester is distinguished as a sort of provincial metropolis, many of the gentry of the neighbouring counties making it a place of occasional residence. Its poorer classes of inhabitants are chiefly occupied in the trades common to a great town, inhabited by opulent families. The only manufacture of consequence is that of gloves, which are made in vast numbers, principally by women. Here are also a small manufactory of tobacco pipes, iron foundries, snuff mills, and large establishments for ship-building, which furnish additional employment. The latter business is carried on to great advantage, many vessels from 100 to 500 tons being built yearly. These, in point of strength and beauty, are reckoned as complete and durable as those built in any other port in the kingdom: the materials are entirely of British oak. Two manufactories for shot, and one for white and red lead, are likewise established here. The shot is exported to America in large quantities.

The maritime business of Chester chiefly consists of the Irish and coasting trades, with a small portion of trade to foreign parts. The quantities of linen cloth imported from Ireland are very great; and for the better accommodation of the merchants, a new hall was erected in the year 1778: this is a handsome square brick building, inclosing a spacious area, and containing 111 shops. Besides linen, there are various other articles both of import and of export; for an enumeration of which, see the article Cheshire. From the large cheese warehouse on the river, vessels are laden with cargoes of this article for London. The limits of the port extend on the Cheshire side of the Dee as far as the end of Wirral, and on the Flintshire side to the mouth of the river Clwyd; yet notwithstanding this, and for all the variety at the same time in the commercial objects here attended to, the number of ships belonging to the port is but small.

The port of Chester was much improved during the last century. The great breadth of the estuary of the Dee, and the comparative smallness of the body of water flowing through it, rendered it liable to be choked up by the sand brought in with the tide; and this gradually took place to such a degree, that in the year 1674 vessels of 20 tons could scarcely reach the town, while ships of burthen were obliged to lie 10 miles farther down below Neston. In that year, accordingly, a plan was devised for the purpose of making a new channel for the river, and at the same time of recovering a large tract of land from the sea by embankment. In the year 1732, a company was established for the execution of this project, through whose exertions, though with much difficulty, and after many losses, a fine canal was made, with high banks, by which the river is confined, for the space of eight miles, with such a depth of water, as to allow vessels of 350 tons burthen to come up to the quays at common spring tides. The cross embankments, made at the same time, have preserved a considerable quantity of land from the sea, and flourishing farms now occupy the space that was formerly bare sand, covered every tide by the water. Two ferries across the canal, or new river, preserve the communication with the opposite country of Wales.

The population of Chester, on an enumeration made in the year 1781, was found to be 14,860. Of this number 6339 were males, and 8521 females; and, by various calculations drawn from the bills of mortality, the proportional healthiness of the city appears to be considerably greater than that of most other towns in England. This may possibly be owing to two causes independent of the salubrity of the air; the situation, viz. of the buildings, on a dry sand-stone rock, and the far less proportion of poor inhabitants than is usual in places whose chief support arises from manufactures. It has been remarked that in this city the number of births is equally disproportionate as that of deaths, to the amount of the existing population.

The city of Chester returns two members to parliament. It was first called to send representatives thither in 34th Henry VIII. who vested the right of election in the freemen, consisting at present of 1200 voters. The religious sects that occur here are associated chiefly in the different classes of Presbyterians, Independents, Quakers, Methodists, Catholics, and the followers of Emanuel Swedenbourg.

The public charities of Chester are numerous. Those more particularly worthy of notice are the Infirmary before mentioned, the House of Industry, the Blue-coat hospital for boys and girls, and the various alms-houses dispersed through the city. The Infirmary took its origen from a bequest of L. 300 left by Dr Stratford, commissary of the archdeaconry of Richmond, and has been increased by voluntary contributions. Before the present building could be prepared for the reception of patients, a temporary infirmary was established in Northgate street, in the year 1756. The new infirmary was opened on the 19th May, 1761, and has been supported by such liberal subscriptions, that the governors have been enabled to administer relief to many thousand persons. The utility of this institution was increased a few years ago by the admission of fever-patients, for whom a distinct ward was appropriated, and due precautionary means employed to prevent any infection from communicating with the other parts of the house. The whole affairs of the establishment are conducted in a judicious and praise-worthy manner. The Blue-coat hospital, which was founded in 1706 by Bishop Stratford, was originally endowed for the complete maintenance of 35 boys for four years, a sufficient sum being allowed to bind them apprentices at the expiration of that time. From the subsequent increase of the funds of the hospital, its utility has been much extended. A school has been established in another part of the building, on the plans of Mr Lancaster and Dr Bell, in which upwards of 130 boys are taught the most useful parts of education. To these monuments of public benevolence, must be added the splendid munificence of Lord Grosvenor, who has erected and supports a school of upwards of 400 boys, and a great number of girls, at his own expence. In another part of the city, a diocesan school is maintained, for the purpose chiefly of instructing youth in Bell's system of education, preparatory to commencing masters. To these may be added several Sunday schools, maintained by public subscription. By these means, all the infant poor receive a competent education. In the Blue School for the education of girls, which is supported by ladies, eight of the girls who are thus provided for, are maintained in board, lodging, and clothes; the others are only clothed. When they leave school, they are placed out to service, and receive each 40 shillings. Of the beneficent institutions in the city, the chief is that for the benefit of decayed freemen of 60 years of age and upwards, 40 of whom are allowed from this establishment L. 4 annually, and a gown every third year. Mr Owen Jones, one of the donors of this charity, bequeathed the profits of an estate in Denbighshire to the poor of the several city companies, who were to receive it in rotation annually. The yearly value of this bequest was originally but a few pounds; but the discovery and working of a rich lead mine on the estate, have so improved the receipts, that the annual income is now nearly L. 400.

A benevolent institution, of a nature before unknown in England, was begun in this city in the year 1774. Its objects were to prevent the natural small-pox from becoming dangerous, by promoting a general inoculation at stated periods, and to keep it from spreading whenever it should break out, by the observance of certain rules drawn up for the occasion. Subscriptions were liberally bestowed for the purposes of this society, and the rules, when steadily observed, were found to be fully efficacious in arresting the progress of contagion; but the supineness of the people, and their superstitious rejection of the offer of free inoculation, rendered the scheme abortive, and it was at length abandoned. The projected plans for its revival have been completely superseded, in consequence of the introduction of the vaccine inoculation.

Between the walls of the city on the west side and the river is an extensive meadow, called the Rood-eye, or Island of the Cross, which in different successive periods has been appropriated to diversity of amusement, and chosen as the place for the exhibition of various feats of bodily activity. It is here that the races are now held, for which, indeed, no situation could be better adapted, the whole lying like an amphitheatre immediately beneath the walls. The season in which these races are annually celebrated is the first week in May.

Chester is supposed to have been founded by the Romans, and indeed plainly appears to have been a station belonging to that people, as well from numerous indications of such an origin and character in its general aspect and mode of structure, as by the many antiquities which have been and still continue to be discovered in and about the town. In the days of that people, it seems to have held a very eminent rank, to have maintained the Roman splendor longer, and to have been later deserted by that people than most other of the British towns; and even to this time the monuments both of its intimate connexion with that race of men, and of its consideration at various subsequent periods, and during the preponderance in the island of other nations, are by much too numerous to admit of being particularly specified in this place. When it was quitted by the Romans, it may be remarked, that the Britons maintained their liberty in it long after the

Saxons had got possession of the rest of the country. From the time that it became subject to the latter people, till the reign of Charles I. it continued to be the constant scene of action between contending parties, and, like every other eminent place in similar circumstances, severely felt the scourge of the ruling factions. Under Henry VII. and VIII. it first enjoyed some respite, and the immunities granted by those monarchs were confirmed by Charles II. out of gratitude to the city for its unshaken fidelity to his unfortunate father. Chester is a bishop's see. It was anciently part of the diocese of Litchfield, one of whose bishops removing the seat of his see hither, A. D. 1075, his successors came to be frequently styled bishops of Chester. It was not, however, till the time of the general dissolution of monasteries under King Henry VIII. that this was erected into a distinct bishopric. This diocese now contains the counties of Cheshire and Lancashire, part of the counties of Westmoreland, Cumberland, and Yorkshire, two chapelries and five parishes in Flintshire; in all 236 parishes, of which 101 are impropriations. Of the livings of the city, St John's is a vicarage, St Olave's a curacy in the patronage of the bishop; the rest are rectories under the same patronage, with the exception of Trinity, which is in the gift of the Earl of Derby.

The annual fairs of Chester, which are among the most noted in England, are held on the last Thursday in February, which is for cattle only; July 5. and October 10, for cattle, Irish linen, cloths, hardware, hops, drapery, and Manchester goods: The two last continue upwards of three weeks. The stated market days are Wednesday and Saturday, when there is an abundant supply brought up of every article of provision. The city is situated in N. Lat. 53° 12′, W. Long. 6° 3′.

CHESTERFIELD, a town of England, in the hundred of Scaresdale, and county of Derby, is situated on the side of a hill, between two rivulets, called the Ibber and the Rother. It is large and irregularly built, and contains few objects that are particularly deserving of notice. The church, which was erected towards the end of the 11th century, is built in the form of a cross, and is both spacious and handsome. Its spire, which is 230 feet high, and is built of timber, covered with lead, is distorted in such a singular manner, that it appears to deviate from the perpendicular in whatever direction it is approached. In the chancel is the burying-place of the family of the Foljambs. Two large altar tombs, and several inscriptions, still remain. Previous to the tenth of Richard I., a hospital for lepers was founded in this town, and continued till the time of Henry VIII. The grammar school, or chapel school as it is called, was founded in the reign of Queen Elizabeth, and was at one time the largest in the north of England. The school-house was built in 1710. An elegant town-hall, comprehending the debtor's gaol, the gaoler's house, and a large room for holding the sessions, was built a few years ago in the market-place; and, about the same time, a handsome assembly room was built at the Castle Inn. The principal manufactures of Chesterfield are stockings, coarse earthen-ware, carpets, and shoes, of which large quantities are annually sent to London. There is also a silk and cotton mill here, and great quantities of lead are sent from this place by the Chesterfield canal which joins the Trent below Gainsborough. The iron works in the town and neighbourhood likewise furnish employment to the inhabitants.

The market is well supplied with corn, lead, malt, leather, stockings, blankets, and bedding, in which articles a very considerable trade is carried on with the neighbouring towns.

In the parish of Chesterfield there were, in 1811,

Inhabited houses	951
Families	973
Families employed in agriculture	51
Families employed in trade	538
Males	2025
Females	2451
Total population	4476

See *Description of England and Wales*, vol. iii. p. 117; and Britton and Brayley's *Beauties of England and Wales*, vol. iii. p. 537. (*w*)

CHESTER-LE-STREET, supposed to be the *Condercum* of the Romans, is a very large and thriving village, situated in a valley to the west of the river Wear, opposite to Lumley Castle. The houses are chiefly arranged in a street about a mile in length, and the principal public buildings are the church, and the deanery house. The church is a handsome stone building with a nave, side aisles and tower, and contains numerous monuments, with effigies of the noble family of Lumley. The spire, which is of stone, is 156 feet high, and is reckoned one of the finest in the north of England. At Whitehill or Whitwell, in the neighbourhood, iron is made of ironstone, dug out of pits. According to the returns in 1811, the parish of Chester-le-Street, which includes the townships of Lambten, Great Lumley, and little Lumley, contains 267 inhabited houses, 273 families, and 1205 inhabitants. See Brayley and Britton's *Beauties of England and Wales*, vol. v. p. 186; and Hutchinson's *Durham*, vol. ii. p. 398. (*j*)

CHIAMPA. See TSIAMPA.

CHIAPA. See GUATIMALA.

CHICHESTER, a city of England, in the county of Sussex, is situated in a level tract of country, on ground a little elevated, and is surrounded on every side but the north by the river Lavant. This town was formerly encompassed with a stone wall, having four gates corresponding with the four cardinal points. From each of these gates was a street which derived its name from the gate, and terminated in the market-place, in the centre of the city. These four principal streets have a considerable width, and are well paved; but the gateways are now destroyed, and only a few parts of the embattled wall remain. One of the remaining portions of the wall is on the north side of the city, where an extensive terrace was raised in 1725, and now forms an elegant promenade.

The principal public buildings of Chichester, are the cathedral, the churches, the market cross, the market house, the guild-hall, the bishop's palace, a theatre, (situated at the bottom of South-street), a work-house, a custom-house, a free school, and some chapels. The cathedral, with the bishop's palace and the houses of the dean and prebendaries, occupy the space between the west and south-west gates. The length of the cathedral from east to west is 410 feet; the height of the central tower and steeple 270 feet; the height of the towers at the west end 95 feet; the height of the tower on the north-west side of the church 107 feet; and the height of the roof or vaulting 61 feet. About a century ago the spire was struck with lightning, and some large stones, one of which was three-fourths of a cwt. was thrown over the houses into West-street. Among the numerous monuments affixed to different parts of the cathedral, one of the most interesting is the monument erected by the inhabitants of Chichester to the poet Collins, who was a native of the town. It is executed by Flaxman with his usual taste and ability. The seven churches are all built with flint stones. In the middle of the market-place is a stately octangular cross, supported on eight arches, highly ornamented, and reckoned superior to any thing of the kind in England. The market house is built of stone, and supported by stone pillars. The guild-hall, though mean, is a spacious and ancient building. The bishop's palace, built in 1727, is more remarkable for its size than its beauty.

The river Lavant is navigable for small vessels. The quay and harbour is about two miles from the town, and four from the sea. Large quantities of salt were formerly made at Chichester, and there was also a great manufacture of needles. Baizes, coarse cloths, and blankets are manufactured here; and ship-building is carried on to a considerable extent.

According to the recent population returns for 1811, Chichester contains

Inhabited houses	1083
Families	1286
Families employed in agriculture	72
Families employed in trade and manufactures	803
Males	2878
Females	3547
Total population	6425

See the *Architectural Antiquities of Great Britain*, vol. i.; and Hay's *History of Chichester*. (*w*)

CHILI.

Chili.

CHILI is a country of South America, stretching along its western coast, and confined on the east by a chain of the Cordilleras. It occupies that space which lies between the 24th and 45th degrees of south latitude, and between the 68th and 74th of west longitude. In treating of this country, we shall comprehend our account of it under two general divisions; the first containing the History, the second the Statistics of Chili.

PART I. HISTORY OF CHILI.

History.

Origin of the Chilese.

FROM a total want of records, the origin of the Chilese is still obscure and undetermined. Their own opinions, as well as their traditions on the subject, are altogether so vague, imperfect, and contradictory, as at best to afford only the means of conjecture. Some of them would lead us to conclude, that Chili was settled from the west; others, that its inhabitants came from the north; and others, that they are indigenous. That America, in general, was peopled from Asia, is an opinion very common and well supported; but it still remains to be decided, whether all its inhabitants are of the same origin, and received from the same point of communication, the north-east of Asia. Molina supposes that Chili, in common with the rest of South America, was originally settled from the southern parts of Asia. In support of this, he alleges the general similarity of language and character, which, to this day, are still observable in their respective inhabitants; and, in order to shew some probable line of communication, has recourse to an ingenious but rather bold conjecture. He imagines, that a vast extent of country has once united the two continents towards the south, but that this, by the gradual encroachments of the Pacific Ocean, has since that time been reduced to a chain of islands. From suppositions of this nature, and with materials such as we have mentioned, it would be vain to pursue an inquiry, which could only betray us into the labyrinths of theory, without leading in the end to any certain or satisfactory conclusion.

The Peruvians invade Chili.

It is to the Peruvian annals that we are indebted for the earliest accounts of Chili, and from them we have nothing prior to the middle of the fifteenth century. At that time the Peruvians greatly surpassed all their neighbours in civilization. They had already brought many of them under subjection, and were soon excited to the conquest of Chili, by the natural advantages of the country, the fertility of its fields, and the delightful salubrity of its climate. Anticipating the difficulties of an enterprise the greatest they had yet undertaken, it was not entered upon without the most cautious deliberation, and nothing was omitted, that might tend in any degree to procure a successful issue. At length, after the minutest enquiries, Yupanqui, the tenth Inca, marched with a numerous army to the frontiers of Peru, and having there established his court in the province of Atacama, dispatched Sanchiruca, with part of his troops, for the subjugation of Chili. Preceded by ambassadors, the Peruvian general entered the country with very slight opposition, and almost without a blow reduced the whole of the southern provinces, as far as the river Rapel. Beyond this was a people very different from the unwarlike tribes, which had already been so easily and rapidly subdued. They were named Promaucians, or *free dancers*, a high-minded people, fond of the peaceful amusements, but still fonder of liberty. They met with vigour the invaders of their independence; and in a battle of three, or, according to some accounts, of six days continuance, completly routed the Peruvians, drove them from their territories, and compelled them to limit their acquisitions in Chili, to those less formidable and already subjected provinces, which lie north of the Rapel. Upon these provinces the Inca imposed an annual tribute of gold, but no innovation was attempted, either in their customs, manners, or government, all of which they were suffered to retain free and unaltered till the year 1535, when Chili was invaded by the Spaniards under Diego Almagro.

Invasion of Chili by the Spaniards under Diego Almagro.

These brave but unprincipled adventurers had already conquered Mexico, and overrun, with incredible success, the whole kingdom of Peru. Still, however, unsatisfied, their avarice and their ambition were yet farther allured, by the rich mines and the beautiful plains of Chili. Almagro left Cusco with 570 Spaniards, and 15,000 Peruvian auxiliaries. Disregarding all the remonstrances of his confederates, he preferred passing the Cordilleras, to the other more distant, but, at that season, less dangerous entrance, by the desert of Atacama. Unfortunately, however, winter had already commenced when they reached the Cordillera Nevada, and, in the course of their passage, the snow fell in such abundance, and the cold became so intense and overpowering, that not less than 10,000 Peruvians, with 150 Spaniards, perished in the march; the rest were happily extricated by the activity of their leader. Almagro with a few horse having reached the plain, procured assistance and provisions for his exhausted soldiers.

They are well received in the northern provinces.

They were received in Copiapo with the most benevolent hospitality, and, in a short time, were completely recovered of their fatigues. The northern provinces had been subdued, and were still tributary to the Peruvians; and here the Spaniards were unexpectedly gratified by the distribution of 500,000 ducats, which Paulu, the Peruvian leader, well acquainted with the views and disposition of his associates, had exacted from the inhabitants, and presented to Almagro. This present gave a strong impression of the riches of Chili, and animated the soldiers in the prosecution of their enterprize.

Cruelty of Almagro.

Before leaving Copiapo, they were joined by reinforcements from Peru; and, in their progress southwards, were every where treated by the natives with liberality and respect. They were even regarded as beings of a higher nature, more allied to divinity than to the common race of mortals. This convenient persuasion was as industriously propagated as it was credulously believed. But we must here notice an occurrence, which served, in no small degree, to undeceive the deluded inhabitants, and to develope, in its true light, the character of their new friends. Two stragglers from the Spanish army being put to death, and we may suppose not without sufficient grounds for the severity, by the people of Guasco, Almagro instantly proceeded to take a cruel vengeance on the offenders. He arrested the Ulmen or governor of the guilty district, his brother, and twenty more of the principal inhabitants; all these, together with an usurper of Copiapo, whom he had lately deposed, were at his command, without even the formality of justice, committed at once to the flames. This conduct of Almagro did not pass without censure; even his own Spaniards were displeased, and openly reprobated the barbarity of their leader. Familiar as they had long been with robbery and slaughter, some were still found among them, who had not utterly renounced all the sympathies of humanity.

Battle with the Promaucians.

Almagro now entered the country of the Promaucians. That gallant people had on a former occasion successfully resisted all the efforts of Peru. At the first appearance of the Spaniards, they stood amazed and confounded. The Spanish horses were the first they had ever beheld; but still more wonderful were the mysterious weapons which these strangers brought along with them. They were surprised, but not intimidated; and both armies drew up for battle, on the shore of the Rio Claro. The Peruvians, whom Almagro had posted in front, were soon broken and routed, and fell back with terror on the Spanish line. The Spaniards themselves were able with difficulty to sustain the furious attack; they were not a little astonished at the resolute valour and fearless impetuosity of their new assailants. The struggle was obstinate, bloody, and doubtful, and night alone put an end to it. The Promaucians, however, remained in sight of their formidable enemy, with a determination to renew the fight next morning. The Spaniards kept the field, and claimed the victory; but a victory of such perilous achievement they had neither expected nor desired, and they were now fully persuaded of what indeed the Peruvians had before warned them, that the country of this people was not to be won by the force of prejudice alone, but by arms and valour, fatigue and bloodshed.

The Spaniards return to Peru.

It is seldom that men have resolution patiently to undergo toil and danger in the attainment of an object, when their anticipations had prepared them for neither. So it happened with the Spaniards; they resolved unanimously to abandon the enterprise. Some of them, indeed, expressed a desire to remain in the country, and form a settlement in the northern provinces, where the natives were of a milder and less warlike disposition. At the request however of their leader, they unanimously returned with him to Cusco, in order to support him in his pretensions to that city. Cusco was included in the grant of territory, which had lately been conferred upon Almagro by the court of Spain; but his rival Pizarro, in whose power it then was, could not be persuaded to abandon so rich a possession. Almagro fell in the contest, and his soldiers were scattered over Peru.

Second expedition to Chili under Pedro de Valdivia.

Notwithstanding the failure of the last expedition to Chili, an object so tempting was not thus to be relinquished. Pizarro, now sole master of Peru, was convinced of its importance, and resolved upon another attempt. For this purpose, he commissioned his own quarter-master Pedro de Valdivia, to the exclusion of de Hoz and Carmargo, who had been nominated by the court of Spain. Valdivia had served in Italy, was possessed of courage, prudence, and activity, and, as an officer, was accounted one of the ablest among the Spanish adventurers. Before leaving Peru, he provided himself with all the requisites of a colony, and having crossed the Cordilleras in summer, entered Chili without loss, at the head of 2000 Spaniards, with a large body of Peruvians.

He lays the foundation of St Jago, and dispossesses the Mapochinians.

Almagro had been well received in these northern provinces, chiefly through the influence and authority of his Peruvian confederates. The inhabitants, however, no longer considered themselves as subject to Peru, which they now understood to be itself a conquered kingdom; and they were likewise better acquainted with the Spanish character. It was no longer veiled under the impious and imposing title of divinity. The period of delusion had passed away, and these iniquitous invaders stood naked and exposed in all their startling deformity. The natives were every where in arms to repel the intrusion; and had their power equalled the animosity with which it was exerted, they must have succeeded in the end; but their weapons and their discipline were alike incompetent. Their most powerful efforts were weak, desultory, and ineffectual, and at best served rather to harass than destroy. Unguided and tumultuous, they made but little impression on the steady valour of their more skilful opponents; and the Spaniards, though frequently interrupted, continued their march, and penetrated into the country, as far as the river Mapocho. It was in this rich and beautiful province, that Valdivia resolved, if possible, to effect a settlement. He laid the foundation of St Jago, and immediately erected a strong citadel for its protection. It was not long before this cautious measure proved the safety of the colonists. The Spaniards were resolved to effect in Chili what they had so cruelly accomplished in Mexico and Peru: they had determined to make its free inhabitants the instruments of their avarice, and, in this manner, to subject them to the most degrading servitude. The Mapochinians, therefore, in whose territory they had now settled, and who seem at first to have given but little disturbance to their operations, quickly began to feel the weight of oppression, and, at the same time, to exhibit rather unequivocal symptoms of uneasiness. Upon the first appearance of disaffection, Valdivia seized and imprisoned their chiefs; but the spirit of freedom was not thus to be suppressed, and such insulting severity had the effect only of exciting a more implacable hostility. Seizing an occasion of Valdivia's absence, they effected a general insurrection, assaulted the town, repulsed its defenders, and demolished the half-raised buildings. The Spaniards were now shut up in their fortress; but the enemy fell in thousands around it, and the trenches were soon crowded with their dead. At length the Mapochinians, after a day of gallant exertion, found themselves compelled to retire, both for the purpose of refreshment, and of recruiting their exhausted numbers. In the mean time, Valdivia, secretly apprised of these proceedings, returned in haste to his friends, joined them with sixty horse, engaged the enemy, at the moment they were preparing for a fresh assault, and, after a furious conflict, defeated and pursued them with overwhelming slaughter. The loss of a battle was a misfortune less severe to the Mapochinians, than the murder of their chiefs. This had been effected, during the assault, by the cruel intrepidity of Inez Saurez, a Spanish female, who fearing lest, in the general confusion, they might regain their liberty, and animate their countrymen, dashed out their brains with a hatchet. The spirit, however, of this enduring people, seemed to rise with their misfortunes. Henceforth they renounced every thought of accommodation with their oppressors. They continued for the space of six years with resolute but unavailing perseverance, constantly harassing, but unable to expel the enemy; till at length a feeble remnant, wasted by the unequal contest, and nobly preferring freedom to their country, they destroyed their crops, and took refuge in the mountains.

Distress of the Spaniards; and conspiracy against Valdivia.

The Spaniards, during these transactions, were not without their share of distress. They had been kept almost in a state of perpetual blockade. Their provisions were long since exhausted or destroyed, the supplies constantly intercepted, and the pittance of grain they were able to raise within range of the batteries, proving insufficient for their support, they were reduced often to an extremity of want. Murmuring and discontent were the consequence, and these grew, at length, into a formidable conspiracy, which at once threatened the success of the expedition and the life of its conductor. The plot, however, was fortunately detected, its authors punished with death, and tranquillity restored; while their toils and their dangers were alike quickly forgotten, in the pleasure of an unexpected gratification. An extremely rich mine of gold was discovered and opened in the province of Quillota. This revived their hopes, and dissipated all desire to abandon an enterprise, now of so much promise.

Increasing hostility of the natives.

From the tedious opposition, already experienced, Valdivia was sensible that, without additional forces, it would be impossible for him to pursue those vast schemes of conquest, which he had formerly projected, and still fondly indulged. The more readily to obtain the necessary supplies, he dispatched messengers to Peru, whose spurs, bits, and stirrups were of solid gold. This he hoped might excite expectation, and procure adventurers. Of these messengers, only two, covered with wounds and stripped of their trappings, escaped with difficulty to Cusco: the rest, with an escort of 30 horsemen, were intercepted and slain by an hundred archers of Copiapo. Large reinforcements, however, both by sea and land, were, by the exertions of Monroy and Miranda, the two survivors, sent off to Chili; and these were followed soon afterwards by 300 more, under the command of Francis Villagran, and Christopher Escobar.

Since the affair of Copiapo, the natives had every day become more daring and troublesome: among other instances of this spirit, the Quillotans, by a successful stratagem, had surprised and massacred all the Spanish miners in their district. These proofs of inveterate hostility determined Valdivia, before extending his conquests, to secure what he had already gained; and at the same time to take means of protecting his future communications with Peru. For these purposes, he erected a fort in the province of Quillota, and shortly afterwards proceeding northwards to the mouth of the river Coquimbo, founded, in 1544, the town of La Serena or Coquimbo.

The Promaucians form an alliance with the Spaniards.

Having completed those requisite measures of security, he now turned his thoughts to the long projected invasion of the southern provinces; and next year led his army against the Promaucians. History does not acquaint us with the progress of this interesting contest; we are informed only of its final result; a result which at once tarnished the glory, and annihilated the independence of that brave and once invincible people, which struck out their names from among the patriots of Chili, and drew upon them, ever afterwards, the execrations and the vengeance of their countrymen. They were ultimately seduced into a most inglorious compact with the Spaniards; and Promaucian auxiliaries have, since that period, supported the Spanish interests in Chili.

In the year 1546, Valdivia had pushed his conquests as far as the river Itata. Here, however, a circumstance took place, which, from a want of vigilance on his part, had nearly proved fatal to the whole army, and gave a check to his victorious career. During the night, his camp was attacked and forced by the natives, and the loss was so considerable as to compel a precipitate retreat.

Notwithstanding his late accession of force, Valdivia still found it unequal to his vast designs; and to complete his embarrasment, Pastene, who had sailed for additional reinforcements to Peru, now returned without having accomplished the object of his mission. He brought accounts of the civil war, between Gasca the royal delegate and Gonzalo Pizarro, who resisted his authority. Valdivia hoping to benefit by these commotions, instantly embarked for Peru, with a resolution to join Gasca, and support the royal standard.

In the mean time his rival in Chili, the unfortunate de Hoz, fell a sacrifice to his jealousy. On pretence of aiming at that government, which, as we have before noticed, was legally his own, he was seized and publicly beheaded by Francis Villagran, who was no doubt sufficiently instructed for this infamous proceeding. About the same time a detachment of Spaniards, to the number of 40, was cut in pieces, in their march from Peru, by the inhabitants of Copiapo; and the Coquimbanes, imitating their vigorous example, extirpated the colony of La Serena. This city, however, was quickly afterwards rebuilt by Francis Aguirre.

After the defeat and death of Pizarro, Valdivia returned to Chili, followed by a crowd of adventurers, men of whose seditious turbulence Gasça was happy to be relieved. Before, however, resuming offensive operations, he distributed the conquered provinces among his adherents; and in this manner effectually secured their fidelity, while he inspired them with a more permanent interest, in the country for which they contended. He now penetrated southwards, without almost any opposition, to the bay of Penco; and, according to his usual policy, took possession of the country, by the establishment of a new colony, and the foundation of another city. To this city he gave the name of Conception: it stands on a fruitful soil, and has a fine commercial situation.

Operations against the Araucanians.

From this period we may date the commencement of a more combined, a more vigorous, and a more successful resistance than the Spaniards had yet experienced. A field of more hazardous contention was now opened to them,—a field in which they were not unfrequently to feel the impotence and the pressure of an unrighteous cause. They were now to encounter, not the timid slaves of luxury and prejudice, but a nation of indignant heroes, roused to exertion in defence of their liberty and possessions, who held in defiance their boasted superiority, and set at naught even "the thundering arms of Europe." This new power was the Araucanians, a name bestowed indiscriminately upon several distinct, though confederate tribes: they occupy that portion of Chili which extends between the rivers Biobio and Callacalla. Regarding with indignation the insolence, the rapacity, and the growing power of these formidable strangers, and perceiving that the next blow must inevitably fall upon themselves, the Araucanians resolved to send immediate relief to their neighbours of Penco. For this purpose, Aillavalu, their *Toqui* or dictator, crossed the Biobio, and, at the head of 4000 men, gave battle to the Spaniards. After the first discharge of musketry, the Chilese, by a bold and dextrous movement, pouring at once upon the whole Spanish line, brought it to close fight, while at the same time the Spaniards, having instantly assumed the form of a square, firmly maintained their ground. The conflict was severe and bloody, and for several hours was bravely supported on both sides. At length Valdivia being dismounted, confusion began to shew itself among his troops; when Aillavalu, eager to seize the momentary advantage, by a rash but gallant impetuosity, fell in the front of battle. His soldiers instantly began to retreat, maintaining, however, so much appearance of intrepidity and order, that the Spaniards dared not to pursue. After the battle Valdivia testified his amazement, at the skill, the valour, and the discipline of his new opponents. He had often encountered all the terrors of European warfare, but never before this engagement had his life been put to such imminent hazard. The boldest of his soldiers dreaded the return of so daring an enemy; and, to prepare for the worst, a strong fortification was immediately erected near the town.

In the mean time, the Araucanians were again advancing with a more numerous army than before, but under the auspices of a very different leader. Lyncoyan, the new Toqui, possessed neither the skill nor the courage of his predecessor. His strength and his stature were enormous, and it would seem that a regard to these, more than to his mental abilities, had exalted him to the vacant dignity. The Araucanians, while under his guidance, seemed to have dropped all the energy of their true character, and the succeeding operations were every where marked with weakness, incapacity, and failure. The Spaniards, however, heard of their approach with some degree of alarm, and immediately drew up under protection of their batteries. But they had little to fear from the irresolute temper of their opponent. The first attack proving unsuccessful, he retreated with precipitation, leaving the enemy in equal joy and astonishment. So powerfully, however, were their minds impressed with the magnitude of the danger, and the importance of their sudden deliverance, that these faithless robbers presumptuously ascribed their safety to the miraculous interposition of heaven. During a whole year, employed by Valdivia to enlarge the city, and settle the affairs of his new colony, no molestation was offered by the Araucanians. At length the Spaniards, recovering from their apprehensions, began to ascribe to the fears and weakness of the enemy, what was due only to the misconduct of their leader. Being newly reinforced from Peru, Valdivia resolved to venture an incursion into their territory. He traversed it with unexpected facility, and was permitted, without almost any resistance, to lay the foundation of three other settlements; of Imperial, (1552,) at the confluence of the rivers Damas and Cauten; of Villarica, by one of his officers, at the great lake Lauquen; and of Valdivia, named after himself, at the southern extremity of Araucania. The better to maintain footing in a country of which he now deemed himself the master, he erected a strong fort in each of the most warlike provinces of Puren, Arauco, and Tucapel. He even proceeded so far as to portion out the country and its inhabitants, among his principal officers. After these important operations, Valdivia retired to St Jago, now as much elated with confidence, as he was formerly depressed by apprehension; and having about this time received fresh reinforcements, his ambition began to grasp at still wider dominion. He commissioned Francis Aguirre to subdue the two provinces of Cujo and Tucoman, which lie east of the Cordillera; while he himself entered once more the Araucanian territories, and founded a seventh city in the province of Encol. He called this the city of the frontiers, an appellation which, at an after period, became strictly appropriate.† About this time also, with a view, if possible, by a direct communication with Europe, to render his future supplies independent of Peru, a vessel was dispatched, under the command of Francis Ulloa, to examine the straits of Magellan.

Prosperity thus shone upon the triumphant Spaniards, but a fatal storm was already gathering among the enemy. Submission was equally intolerable and repugnant to the haughty spirit of the Araucanians, and it required but little persuasion to excite them to more vigorous measures. By the exertions of Colocolo, an aged Ulmen, the chiefs were assembled, Lyncoyan deposed, and, after a violent altercation about the supremacy, the choice of a new Toqui was unanimously submitted to the prudent Colocolo. He immediately directed their notice to Caupolican, of a genius at once enterprizing and cautious, but whose modesty had hitherto prevented his appearing as a candidate. A shout of enthusiastic applause proclaimed his election; and scarcely had he assumed the badge of authority, when he had to repress the fiery zeal of his countrymen, who demanded instantly to march in quest of the enemy. After sufficient preparation, he led them against the forts of Arauco and Tucapel, both of which, after a short siege, he forced the Spaniards to evacuate; and, on the ruins of the latter, waited the approach of Valdivia, who was in vain hastening to its relief. The two armies soon met, and the first onset proved auspicious to the Araucanians. The enemy's left wing, pushing forward to meet their

† Its ruins now stand as a boundary mark between the Araucanian and Spanish territories.

Defeat and death of Valdivia.

attack, was surrounded and cut in pieces. A second detachment fell in the same manner. As the conflict, however, became general, the tide of success was for a while balanced, and began at length to flow heavily against the Araucanians. The Spanish artillery penetrated, with dreadful effect, their compact and crowded battalions. Twice had they been repulsed in disorder, when a third discomfiture completed the confusion, and baffled all the efforts of Caupolican to renew the combat. At this critical moment, the famous Lautaro, a young Araucanian, the captive and page of Valdivia, seized with a patriotic enthusiasm, darted from the hostile ranks, upbraided, rallied, and at length brought his indignant countrymen with such fury to the charge, that the first encounter proved completely decisive; and with such fatal promptitude did he pursue the advantage, that, excepting their general who was made prisoner, not a single Spaniard escaped the slaughter: Only two Promaucians reached Conception with intelligence of the battle. Valdivia condescended to ask his life of the conqueror, promising to quit Chili with all his countrymen; and Caupolican, influenced, as well by his own generous temper, as by the intercession of Lautaro, shewed an inclination to spare him. An old Ulmen, however, more prudent than humane, exclaiming against the folly of trusting to the oaths and the promises of an ambitious adversary, and furious at the thoughts of his escape, secretly approached the prisoner, and dashed out his brains with a blow of his club. A severe punishment would have quickly followed this precipitate conduct, but for the obstinate interposition of the Araucanian officers.

This important victory produced the evacuation of Puren, and the abandonment of Villarica, and the city of the Frontiers. It was celebrated by the Araucanians during three successive days, whilst the heads of their fallen enemies were suspended with savage exultation, around the place of festivity. Lautaro, who, at the early age of sixteen, had thus gloriously achieved the salvation of his country, was created lieutenant-general extraordinary, and entrusted with the command of a separate army; and Caupolican laid siege to Imperial and Valdivia, the only places of strength in Araucania that now remained to the Spaniards.

Francis Villagran succeeds to the government.

army.

The accounts of Valdivia's overthrow and death, filled the inhabitants of Conception with the utmost dismay. The instructions being opened, which he had entrusted to the magistrates of that city, it was found that three persons, Alderete, Aguirre, and Francis Villagran, were nominated to succeed him in the government; but neither of the two former being present in Chili, the command devolved upon Villagran. This gallant officer, less intimidated by the late disaster than impatient to revenge and repair it, immediately upon his accession to the government, levied a considerable army, and marched in quest of the Araucanians. In expectation of his approach, and with a resolution to oppose his passage, the young Lautaro had taken a strong position on the hill of Mariguenu. Villagran soon arrived, attacked him with all his forces, and, after a furious and obstinate contest, was at length totally routed. He effected his own escape to Conception with the greatest difficulty, being attended only by a few horse, and leaving on the field of battle the greater part of his soldiers. Not conceiving the town to be at all tenable against the efforts of a triumphant and vigorous enemy, he embarked in haste the old men, women, and children, to be conveyed to Imperial and Valparaiso, and with the remaining inhabitants marched by land to St Jago. Lautaro soon after conducted his victorious followers into the deserted city, and enriched them with its plunder.

During these operations, Caupolican had pressed the sieges of Imperial and Valdivia; but Villagran, being apprised of their danger, and having succeeded in throwing into them sufficient reinforcements, the Araucanian general discontinued the attempt, and with a view to some more important enterprize, united his army with that of Lautaro.

First introduction of the small-pox into Araucania.

About this period, the small-pox, that pestilence to the New World, which a few years before had appeared in the northern provinces, was now for the first time introduced into Araucania, during a predatory excursion from the town of Valdivia, by the Spaniards. Its effects were awfully destructive. One district, in particular, was almost completely depopulated. Of twelve thousand persons, not more than a hundred survived its ravages.

Conception rebuilt, and again demolished, by Lautaro.

In addition to the late misfortunes, the Spaniards were now menaced with a civil war. Francis Aguirre, whose pretensions to the government were superior to those of Villagran, upon information of Valdivia's death, had relinquished his unpromising attempts upon Cujo, and returned to claim the command in Chili. Happily, however, for the colony, the two rivals were induced to submit their pretensions to the court of Audience at Lima. After an expedient to satisfy both parties, by favouring neither, Villagran was, at the petition of the colonies, confirmed in his command; being invested with the more humble title of Corregidor. From the same court, he received instructions to re-establish the settlement of Conception. This he complied with, less from a concurrence in the measure, than from a desire to prove his submission. But he was not suffered to remain long unmolested, in the neighbourhood of so vigorous an adversary. Lautaro met him in the field, with two thousand men, was again victorious, and once more laid in ruins the city and its fortifications.

Lautaro marches against St Jago, and is slain.

While Caupolican resumed the sieges of Imperial and Valdivia, his active lieutenant, at the head of six hundred chosen companions, undertook to employ the enemy in another quarter. He conceived the bold design, by attacking St Jago itself, to strike a blow at the centre of their power in Chili. Immediately he began his march, and penetrated to the river Maulé without offering the least violence to the natives: but the moment he entered the Promaucian territory, he gave a loose to his indignation, and with more justice than policy, took a dreadful vengeance upon these traitorous apostates, whom, by conciliating, he might have recalled, perhaps, from their hated allegiance. He then fortified himself in their territory, in place of marching directly upon St Jago; a delay which proved fatal to the success of the enterprize. The inhabitants were quickly informed of his approach; but, lying at the distance of three hundred miles from Araucania, they at first only ridiculed the information, and could scarcely credit the possibility of so daring an attempt, till it was fully ascertained to them, by the surprise and defeat of one of their detachments. Villagran, being unable himself, from indisposition, to head the forces, gave the command to his son Pedro, with instructions to march directly against the enemy. Pedro attempted in vain to force the Araucanian encampment, and was repeatedly discomfited. A bold stratagem of Lautaro's had nearly overwhelmed his whole army: by turning upon it, during the night, a branch of the river Mataquito. Having escaped this disaster, he soon afterwards laid down the command to his father, who found himself in a condition to resume it. Villagran had now been taught respect for his adversary; and dreading the consequence of a pitched engagement, resolved if possible to take him by surprise. Conducted by a secret path, he reached at day-break the Araucanian camp. At the first alarm, Lautaro, who had just retired from the fatigues of a night's watch, was in a moment at the head of his troops; and, at the same instant, was seen to drop, pierced to the heart by one of the enemy's darts. The exulting Spaniards pressed furiously upon his dispirited soldiers, the meanest of whom would have willingly exchanged fates with his beloved commander, and cared not to survive him. But the triumph was dearly purchased. Not a man of that chosen band would submit to yield himself a prisoner. They spurned at the offered mercy; and after a long and bloody resistance, the few that still remained, despairing to find death, while they continued to deal it so profusely around them, threw themselves on the spears of the admiring and reluctant enemy.

The extravagant rejoicings which the Spaniards manifested on this occasion, and which were continued for three days in succession, throughout all the settlements in Chili, sufficiently testified the importance attached to the victory. Nothing could better celebrate the merits of the young hero, in whose destruction they so exultingly triumphed, and which they regarded as itself a full equivalent for all their disasters. Like Marcellus of Rome, he was the sword of Araucania. His powerful genius supplied the want of experience; and during his short and brilliant career, success never forsook him. The beauty of his person was equal to the energy of his mind. His memory is still fondly cherished, and he is still the boast of his country, as he was formerly its glory and protection.

Don Garcia de Mendoza supersedes Villagran in the command.

Villagran was superseded in command by Don Garcia de Mendoza, who arriving from Peru with a large body of recruits, landed near Conception, (1557), in the small island of Quiriquina. Some of its inhabitants, who pretended to dispute the debarkation, being made prisoners, Garcia commissioned them with offers of peace to the Araucanians. Though Caupolican and the other chiefs were well convinced of the insincerity of this overture, they determined, after some debate, to meet it with a like appearance of candour. From this mode of acting, they proposed to themselves at least one advantage: they hoped to procure information of the designs and power of the enemy. Millalauco was appointed ambassador, and the Spaniards received him with the most splendid military parade. After the conference, which ended, to the disappointment of neither party, in vague offers and general professions, they conducted him, with equal ceremony, through every part of the camp; and, in order to dazzle and intimidate him, their whole strength (what he secretly desired) was laid open to his minutest observation. Upon the return of Millalauco, his countrymen instantly prepared for war.

Defeats the Araucanians, and treats the prisoners with severity.

The first operation of Garcia was the erection of a strong fortress, on the top of Mount Pinto, which commands the harbour of Conception. This the Araucanians in vain attempted to storm;[*] and soon after the Spanish commander, having collected all his forces, crossed the Biobio, and defeated them with considerable slaughter. On this occasion, the cruelty of Garcia to the prisoners was a portentous prelude to his future barbarities. Those of them who escaped with life, were disfigured and mutilated in a shocking manner. Such proceedings, in place of intimidating a warlike people, and hastening their submission,[†] excited only their abhorrence and contempt, and roused even their indignant females to assume the trade of destruction, and, by the side of their husbands, to share, with masculine valour, in the toils and perils of battle.[‡] And though the Spaniards, during the whole of Garcia's administration, maintained a decided superiority, this should rather be imputed to the strength of the Spanish army, the greatest that had yet appeared in Chili, than to the effect of those infamous inflictions. At the battle of Millipuru, which took place soon after the last, the Araucanians, by feats of the most adventurous gallantry, were on the point of obtaining a complete triumph, when their own furious impetuosity saved the Spaniards. A Spanish body of reserve, profiting by their confusion, restored the battle, and secured their defeat. Among the prisoners were six Ulmens, all of whom were sacrificed to the cruel policy of Garcia, and displayed at their execution a magnanimity which should have drawn his esteem and admiration: but the sordid hearts of these tyrants, engrossed only with the schemes of their own selfish ambition, were shut against every manly and generous sentiment; and such, at that period, was the grossness of their depravity, that, to manifest, but for once, a single feeling of human sympathy, a disposition only to alleviate the horrors of oppression, was sufficient to gain for its author the exalted title of humanity.

Garcia having thus given a farther display of his sanguinary temper, marched into the heart of Araucania, and on the memorable scene of Valdivia's overthrow, built and fortified the town of Canete, provided it with a numerous garrison under Alonzo Reynoso, and returned in triumph to Imperial.

Caupolican fails in his attempt upon Canete.

Canete was quickly assaulted by the Araucanians, but with more valour than success. At length, the irritation of defeat and disappointment, drew Caupolican from his usual caution, and made him for once relax from the stern dignity of the national character. In his eagerness to destroy the enemy, he entered into a plot, in which, from a sense of honour, the other chiefs disdained to participate, and which, in its execution, was turned against himself, and proved the destruction of his brave army. A Chilese, one of the Spanish auxiliaries, was engaged to deliver up Canete to the Araucanians. The traitor, however, played a double part. He discovered the whole transaction to Reynoso, who having taken the necessary measures, admitted a part only of the Araucanian forces, overpowered and cut them to pieces; while the cannon of the place, and a charge from the Spanish cavalry, completed the destruction of those without. Caupolican was among the small number that escaped, and with a few domestics took refuge in the mountains. Three Ulmens, taken alive, were blown to pieces from the mouths of cannon.

---

[*] "During the attack, Tucapel, an Araucanian chieftain, hurried on by his unparalleled rashness, threw himself, like another Turnus, into the fort, and killing four enemies with his formidable mace, escaped, by leaping over a precipice, amidst a shower of balls."—*Molina.*

[†] "Among the prisoners was one more daring than the others, called Galverino, whose hands Don Garcia ordered to be cut off. He returned to his countrymen, and showing his bloody mutilated stumps, inflamed them with such fury against the Spaniards, that they all swore never to make peace with them, and to put to death any one who should have the baseness to propose such a measure."—*Molina.*

[‡] Hence was probably derived the fable of the Chilian Amazons.

Garcia leads his army through the country of the Cunches, and discovers the Archipelago of Chiloe.

In the confidence that Araucania was now in a state of security, Garcia projected an expedition southwards; and leaving instructions for the rebuilding of Conception, led his army against the Cunches. This people, by the advice of an Araucanian exile, adopted a singular expedient for averting the threatened invasion; an expedient, however, perfectly suited to the sordid temper of their invaders. While the inhabitants concealed their property in the woods, an embassy, fitted out in all the semblance of poverty and wretchedness, was dispatched to meet the Spanish commander. The whole appearance of these ragged messengers, with the present they laid before the governor, while it excited the mirth, repressed the ardour of his soldiers. But Garcia, though himself deceived, encouraged them with the hopes of a happier country beyond this miserable region, and required a guide from the inhabitants. One of the ambassadors undertook this office. In order to support the delusion, he conducted the Spaniards by a rough and desolate route, along the sea coast, and after four days march, having entangled them amidst a desert of precipices, secretly returned to his friends. After surmounting the severest privations, the Spaniards were at length gladdened with the prospect of relief, when, on the 31st of January, they came in sight of the great Archipelago of Ancund, or Chiloe, which lay extended before them. They were saluted by the hospitable natives with a frank and fearless cordiality, and supplied in abundance, and gratuitously, with fish, fruit, and maize. These Islanders had evidently attained some degree of civilization. They were handsomely clothed; agriculture was practised among them, and in some of the islands had made considerable progress: they employed sails, also, in navigating their periaguas. Pleased with the discovery, Garcia returned to Imperial, one of the friendly Chilotes serving as a guide to his army; and in passing through the country of the Huiliches founded, or, according to some, only rebuilt the town of Osorno.

Caupolican taken and impaled.

In the mean time, the illustrious Caupolican was betrayed into the power of Reynoso, and ignominiously impaled. Reynoso, after the infamous example of his superior, had long attempted, by tortures and promises, to procure intelligence of his retreat. A traitor at last appeared among that faithful people. Under his guidance, a Spanish detachment was conducted to the mountains, and surprised the general in the midst of his family. The conduct of Caupolican's wife upon this occasion is remarkable, and affords one example, among many, of that lofty and implacable temper, which has long supported, and still supports, the independence of Araucania. Perceiving that Caupolican, notwithstanding her unceasing exhortation, that he should die rather than surrender, had, after a brave resistance, yielded himself to the enemy, she tossed after him her infant son, with this haughty exclamation, that "she would retain nothing that belonged to a coward."

His son Caupolican the Second succeeds him in the Toquiate.

The Araucanian spirit was effectually roused by the insulting execution of their Toqui. Young Caupolican, who inherited the talents and cool intrepidity of his father, was immediately elected in his room. Twice he defeated the Spaniards under Reynoso, but failed in his attempts upon Imperial, where Garcia commanded in person. The succeeding operations were conducted with various success. Many battles were fought, but with little advantage to either party. At length, Caupolican, perceiving that the enemy were continually strengthened with fresh reinforcements, and himself weakened even by success, determined to prolong the war; and, for this purpose, fortified his army in a position almost impregnable at Quipeo. Here Garcia brought all his troops to the assault. The fierce Araucanians, impatient under a galling cannonade, were soon drawn to a rash and furious sally. The Spaniard saw his advantage, cut off their retreat, and after a severe struggle, which, for many hours, remained doubtful, succeeded in overpowering them. The Araucanians were almost exterminated. The loss of Caupolican, Tucapel, and Colocolo, with most of their bravest chieftains, was the bitter fruit of their temerity. Caupolican, finding retreat impracticable, is said to have perished by his own hands, rather than yield himself a prisoner.

Is defeated at the battle of Quipeo, and puts an end to his life.

It was now concluded, with some appearance of reason, by the Spaniards, that the bold spirit of the enemy was at length completely subdued; but the event once more deceived them. They had still to be taught the supremacy of freedom, of that native enthusiasm, that enduring energy, and that gallant perseverance, which for ever accompany, characterise, and render altogether invincible the efforts of a free and high-minded people. While they were yet exulting in joyful anticipation, a new Toqui was elected by the relics of Quipeo. The few remaining Ulmens, more resolute than ever to maintain their freedom, assembled in a wood, and exalted to the supreme command Antiguenu, a man of low rank, but whose talents entitled him to the preference. He retired, with his little band, to the inaccessible marshes of Lumaco, where it was proposed to concentrate their shattered resources, and strike once more for the deliverance of their country.

Antiguenu elected Toqui.

Reduction of Cujo by the Spaniards.

While these matters were secretly transacting among the enemy, Garcia, finding himself possessed of a large disposable force, dispatched Pedro Castillo for the reduction of Cujo. More successful than Aguirre, he succeeded in establishing in that country the colonies of St Juan and Mendoza. Francis Villagran was about this time reinstated by the court of Spain in his former command, and Garcia, in consideration of his eminent services, was transferred, at the same time, to the government of Peru.

The command restored to Villagran.

Antiguenu defeats the enemy, and lays siege to Arauco.

Antiguenu, when he found himself in a condition to annoy the enemy, sallied from his retreat. Though his first attempts, from the inexperience of his soldiers, were feeble and unsuccessful, he soon taught them to conquer, to confide in their own strength, and in the conduct of their leader; and having obtained some slight advantages over the Spaniards, seized upon the strong position of Mariguenu. Villagran himself, being at this time indisposed, one of his younger sons advanced to dislodge the Araucanians, but lost, in the attempt, both his own life, and the flower of his army. This defeat was followed by the immediate evacuation of Canete and the loss of Villagran, whose death, accelerated by grief, anxiety, and disappointment, was much regretted by the Spaniards, who regarded him as a brave and prudent leader. Pedro his eldest son, respected for the same estimable endowments, was appointed to fill the station of his father. The Araucanians set fire to Canete, and levelled its fortifications with the ground. Antiguenu then undertook the siege of Arauco, with a body of 4000 men, but in order to create a diversion detached a part of them to invest Conception. The siege of Arauco is remarkable for the signal vengeance which this general contrived to obtain upon the Chilese auxiliaries, by whose intelligence his best officers were perpetually marked out, for the aim of the Spanish artillery. By means of secret emissaries, the Spanish commander was made to suspect their fidelity; and in the violence of his displeasure, in spite of all their remonstrances, having driven them from the fortress, would not permit himself to be undeceived, till he beheld the wretched victims of his credulity suffering a cruel death in front of the Araucanians. During the siege also, took place one of those single combats, which about that period had become frequent. Antiguenu challenged Bernal, governor of the fort. The chieftains met mid-way between their respective forces, and after maintaining a sharp conflict for two hours, were separated by their attendants, and returned to their accustomed mode of warfare. The garrison, pressed by scarcity of provisions, and under a strict and vigilant blockade, was at length reduced to extremity, but were generously permitted to withdraw unmolested by the Araucanians.

which is evacuated by the Spaniards.

Antiguenu having in this manner dislodged the enemy from their two principal forts, and delivered the greater part of his country from their oppressions, began to harass them in their own territories. He dispatched Lilemu, a gallant officer, to ravage the provinces of Itata and Chillan, while he marched in person to the siege of Angol. But a period was here put to his victorious career. Whilst encamped at the confluence of the Biobio and Vergosa, his forces were attacked by Bernal, with the whole Spanish army, and totally routed. Antiguenu perished in the flight. Being hurried along with the fugitives, he was precipitated from a steep bank into the river, and there drowned. In this action the Araucanians are said to have employed, with some dexterity, the muskets they had taken at Mariguenu: and the Spaniards entirely owed their success to the resolute temper of Bernal, who, perceiving his infantry every where yielding to the fierce valour of the enemy, charged the fugitives with his cavalry, restored the fight, and thus wrested a victory of which he had begun to despair. The loss of their Toqui was followed by another scarcely less severe to the Araucanians. The brave Lilemu, who, during these events, had been successful in Chillan, fell a glorious sacrifice to his magnanimity. Coming to the relief of a small detachment which had been overpowered by the Spaniards, he seized a narrow pass, and with a few gallant companions, at the expence of their lives and his own, sustained the whole shock of the enemy; while an easy retreat was thus opened and secured for his scattered soldiers.

The Araucanians defeated with the loss of their Toqui.

A weakness consequent upon the late misfortunes, or partly perhaps having its origin in the cautious temper of Paillataru, the new Toqui, gave the Spaniards an opportunity of regaining their possessions. Rodrigo de Quiroga, by whom Pedro had been supplanted in the government, availing himself of one or other of those circumstances, rebuilt Arauco and Canete, raised a new fortress at Quipeo, and laid waste the country.

The following year a company of sixty men under Marshal Ruiz Gamboa paid a second visit to the Archipelago of Chiloe, where, over a multitude of seventy thousand natives, this little band, without one stroke of resistance, was permitted to establish their abhorred tyranny.

Changes in the government.

An extraordinary fluctuation happened about this time in the form of government. In 1565, a court of royal audience was established by Philip II. to which was entrusted the civil and military administration of Chili. This court immediately dismissed Quiroga from his employment, and bestowed the command upon Ruiz Gamboa. Next year, however, on pretence of being inadequate to the purposes of the institution, it was stript of its authority, and the whole power transferred to the person of a single chief, Don Melchor de Brava, with the titles of president of the Royal Audience, governor, and captain general of Chili. The court itself was finally abolished in 1575, when Quiroga was restored to his former authority; but being already advanced in years, did not long enjoy his restitution. At his death (1580) he was again succeeded by Gamboa. During these rapid transitions in the government, many ineffectual though sincere endeavours had been used to bring the enemy to negotiate. The jealous Araucanians, however, continued to avoid, with unconquerable firmness, the slightest advances to an accommodation with a victorious enemy; an enemy whose whole temper and conduct, as well as their avowed designs, served only to excite hostility, and perpetuate disaffection. The war was continued with redoubled animosity. Paillataru was defeated in the neighbourhood of Canete, and the Spaniards, in their turn, under Melchor de Brava, lost another army on the fatal height of Mariguenu.

The Araucanians refuse to negotiate.

After another severe engagement, from which the Spaniards could only claim a victory by remaining masters of the field, the contending powers seemed to have been mutually awed into peace, by the ravages of a tremendous earthquake. Conception was completely demolished, and the other settlements experienced considerable injury. The truce lasted four years, at the expiration of which, on the death of Paillataru, hostilities were renewed. In the election of another Toqui, the Araucanians exhibited some political address. In order to engage the confidence and conciliate the affection of the Mustees, who by that time had exceedingly multiplied in the country, they exalted to the supreme power Paynenancu, one of their number. This chief had served with honour in their armies, and was possessed of courage and activity to a great degree; but his disposition was at the same time rash and presumptuous, and too frequently impelled him to undertakings the most daring and impracticable. He seldom hesitated to engage the Spaniards with inferior forces; and from this cause it was that most of his enterprises, though sufficiently harassing, and often destructive to the enemy, were still more injurious to the Araucanians.* That vigorous and haughty spirit, which had hitherto defied adversity, now manifestly began to flag under a constant succession of defeat and disappointment. In the first years of his command, the Pehuenches and Chiquillanians were persuaded, for the first time, to take a part in the contest, and made inroads upon the Spanish settlement of Chillan. Gamboa, who a few years before under Quiroga established this colony, was now himself at the head of affairs, and the short period of his government was wholly engaged in repelling these incursions, and maintaining the war against Paynenancu.

An earthquake destroys Conception.

He was superseded in 1583 by Don Alonzo Sotomayor, who arrived in Chili with six hundred regular troops. This officer supported the war with a powerful superiority. The impetuous Paynenancu was decisively worsted in three successive engagements, and the Pehuenches expelled from Chillan. But his fame was deeply tarnished by exhibitions of barbarity. He resumed in all its rigour the detested system of Garcia, and even aggravated its horrors by additional inflictions, and more extended ravages. His course through the country was marked with rapine, devastation, and bloodshed. It presented every where a scene of unexampled atrocity; the hamlet yet smoking from the hand of the destroyer; its late happy tenant suspended lifeless or in torture from his chosen

Sotomayor adopts the cruel system of Garcia, and maintains a superiority in his operations against the Araucanians.

---

* Soon after assuming the command, he was defeated by the quarter-master Bernal, when several Araucanian females were taken in arms. Most of these preferring death to servitude, or fearing perhaps the brutality of their licentious captors, killed themselves during the night.

tree. Others, by a merciless indulgence, as if to spread still wider the face of calamity, were permitted to escape with life, driven mangled and helpless from their habitations, to stretch forth their mutilated arms, and implore vengeance on the oppressor.

Such iniquitous measures did not fail to raise up new opponents. Mustees, Mulattoes, and even Spaniards, went over to the enemy. In aggravation, however, of their late misfortunes, their little army, consisting of 800 men under Paynenancu, venturing to engage the whole Spanish forces, was cut off almost to a man, and their intrepid leader taken and executed. In this deplorable exigence, extraordinary efforts were exerted to retrieve their sinking affairs. Messengers, with symbolical arrows, were speedily dispersed through the country, and at length succeeded in mustering a respectable force. But the Spaniards still maintained a formidable ascendency. The Toqui Cayencura having lost several engagements, and finding his designs against the fortress of Arauco completely frustrated by another defeat, retired in disgust, resigning the command to his son Nangoniel, who was soon after slain in an ambuscade.

The English make a feeble attempt upon Chili.

At this period, (1586) the English made a feeble effort to supplant the Spanish interests in Chili. Sir Thomas Cavendish, with only three vessels, landed a few troops at the port of Quintero, and began tampering with the natives. He was soon attacked, however, and driven off by the corrigidor of St Jago.

The succeeding Toquis, Cadeguala, Guanaolca, Quintigenu, and Pailaeco, though each could boast of some gallant exploit, were none of them able to expel the enemy. The first fell at Puren in single combat with Garcia Ramon, commander of the place. Guanaolca succeeded in capturing the forts of Puren, Trinidad, and Spirito Santo, but effected nothing more of importance; and the Spaniards were still left masters of the country. The period, however, of this toqui's power, was sufficiently signalised by the retributory valour of Janiqueo, an Araucanian heroine, who, stimulated by the loss of her husband to gird on the sword of vengeance, and, in conjunction with her brother, heading a troop of Puelches, carried devastation through the colonies, and severely harassed the operations of the Spanish army. She was at last, however, entirely defeated on the mountains of Villarica, with the complete dispersion of her followers. Quintiguenu began his short career with all the ardour and expectation of a youthful hero. He carried by assault the fort of Mareguenu. The Spaniards assailed it in turn, and were, for the first time, victorious on that celebrated mountain. The young Toqui performed all that glory could inspire, and perished with the greater part of his army. Pailaeco, like Nangoniel, fell in his first enterprise, not a single Araucanian having escaped the slaughter.

Exploits of Janiqueo, an Araucanian heroine.

Succeeding operations.

Thus after a rapid succession of seven Toquis, none of whom were deficient in courage, and some of them exerting a degree of military energy which merited, and at first seemed to promise a more prosperous event, the Spaniards still maintained possession of the country. Both parties, however, were extremely exhausted, and while the Araucanians, with their new Toqui, returned once more to the marshes of Lumaco, the Spanish commander finding his forces so much reduced, as to render impossible the vigorous prosecution of his advantages without very considerable reinforcements, went in person to Peru, for the purpose of more readily obtaining them. At Lima he met with Don Martin Loyola, commissioned to supersede him. This officer, on his arrival at Conception, was visited by a deputy from Paillamachu, whose true purpose by the message was not merely, as pretended, the formality of congratulation, but, if possible, under that pretence, to discover the views and temper of his new antagonist.[*] The period of Loyola's government was singularly unfortunate. He began his administration by founding (1594) the city of Coya, intended for the double purpose of protecting the mines of Killacoya, and as a place of retreat for the inhabitants of Angol; but he could not save the colonies from the predatory incursions of Paillamachu. This aged Toqui led forth his soldiers, in 1596, to gather subsistence from the enemy's territory, and by the rapidity of his movements eluded all pursuit. He took by storm the fortress of Lumaco, which, in order to repress his excursions, had been erected on the borders of the marsh. Soon afterwards, by one fortunate blow, he redeemed the liberties of his country. Loyola returning from Araucania, had, upon reaching the frontiers, dismissed the greater part of his escort, when Paillamachu came upon him during the night with 200 men, surprised him in his rash security, and slew him with all his attendants. This exploit seems to have been confidently anticipated by the Araucanians, and, by previous concert, was appointed the signal for a general insurrection. Within two days, all the Spanish settlements from the Biobio to the Archipelago of Chiloe were attacked by the enemy, and their cities closely invested. While the victorious Toqui, seizing this moment of surprise and trepidation,[†] crossed the frontiers, took Conception and Chillan, ravaged the provinces, and loaded his troops with their plunder. Notwithstanding, however, the general consternation, Pedro de Viscaza, with what troops he could muster, boldly entered Araucania, and happily succeeded in withdrawing the inhabitants of Angol and Coya. With these he re-peopled the deserted cities of Conception and Chillan. Their apprehensions were considerably allayed by the arrival of Don Francisco Quinones as governor, with a supply of soldiers and military stores. Still, however, the numerous sieges in Araucania were pressed with vigour by the natives, and some indecisive engagements produced the evacuation of Canete and Arauco, while the disappointed Quinones vented all the fury of his unmanly temper on a few wretched captives. Shortly afterwards Valdivia fell into the hands of Paillamachu, who stormed its fortifications, after swimming with his troops across the river. Its capture put the enemy in possession of two millions of dollars, a great number of cannon, with four hundred prisoners.

Paillamachu kills Loyola the governor, and delivers his country from the Spaniards.

In addition to these misfortunes, the Dutch with five ships of war plundered the island of Chiloe, and massacred its garrison. Upon landing, however, on the island of

---

[*] The deputy's reply to Loyola, when the latter had indulged himself in expatiating on the vast power and resources of the Spanish monarch, and the ultimate necessity of accommodation on the part of his enemies, affords an evidence of those lofty principles of independence, so ardently cherished by his countrymen. We give it in the words of Molina. "We are not ignorant," said the Araucanian, "of the power of your prince, which extends from east to west. But we are not to be despised; for although we are but a small people, we have hitherto resisted his immense power. Your ideas respecting peace are very different from ours. By peace we understand an entire cessation of hostilities, which is to be followed by a complete renunciation on your part of any pretended right of controul over us, and the restoration of those lands you have occupied in our territories. You, on the contrary, under that name, seek to subject us, to which we will never consent while we have a drop of blood in our veins."

[†] On the first emotions of terror, the inhabitants of St Jago resolved to quit the country, and remove to Peru.

Talea, they were repulsed with loss by the inhabitants, who seem to have mistaken them for Spaniards.

Forbearance of the victorious Araucanians.

These accumulating reverses were quite overpowering to the puny spirit of the governor, and he desired permission, which was granted him, to resign the command. Neither the experience of Garcia Ramon, nor the valour of Rivera, who had signalised himself in the low countries, could retard the fall of Imperial,[*] Villarica, and Osorno.[†] This happened in the course of 1602, under circumstances of extreme privation.[‡] The treatment of the prisoners, who by these successes fell into the power of the Araucanians, affords a noble instance of generosity and forbearance. They were distributed among the inhabitants, and though a few fell into brutal hands, and were treated with severity, not one of them was, according to the example of the Spaniards, either mutilated or impaled. The married were in general allowed to retain their wives, while others had permission to unite themselves to the females of the country: and when an exchange of prisoners took place, some of them who had families preferred remaining with their captors. Such was the conduct of a people, who, by acts of the most ferocious barbarity, had been too frequently provoked to retaliate, and who, in that instance, possessed the full means of retribution.

The Spanish army cut in pieces by the Toqui Huenencura.

The misfortunes of the Spaniards did not cease with the life of Paillamachu, who died at the close of the year 1603. Garcia Ramon, upon his second succession to the command, having been largely reinforced, entered Araucania at the head of three thousand regular troops, besides auxiliaries; an army which was fondly regarded by the colonists as the certain means of re-establishing their tyranny, and wiping out the stain of their calamities. He constructed a fortress in the province of Boroa, which, however, the garrison was shortly compelled to evacuate. The Spanish army then commenced its ravages in two divisions; these were separately attacked by the Toqui Huenencura, and with such admirable dexterity and overpowering success, that he destroyed or captured them to a man.

Re-establishment of the court of Royal Audience.

Induced by these repeated disasters, the court of Spain decreed a permanent establishment of two thousand regular troops to be maintained on the frontiers; and in 1609, after its suppression for thirty four years, restored the Royal Audience. Garcia once more crossed the Biobio, and somewhat retrieved the disgrace of his late overthrow by defeating the Araucanians. He died soon afterwards in the town of Conception, regretted by the Spaniards, and respected even by the enemy for his honour and humanity. Huenencura did not long survive him. The succeeding Toqui Aillavalu the second, has been ranked among the greatest of Araucanian generals, but his fame has outlived the memory of his exploits.

Negotiations for peace

In the year 1612, in consequence of the complaints of Luis Valdivia, a Jesuit missionary, who zealously represented to the king the impracticability of propagating religion amid the tumult of arms, great exertions were made, on the part of Spain, to accomplish a treaty. Philip III., a bigotted though devout monarch, issued commands for a suspension of hostilities, and commissioned Valdivia with full powers to negotiate a peace. Aillavalu, suspicious of the enemy, paid little regard to their professions. But his successor Ancanamon, after minute inquiries, entered sincerely into proposals for an accommodation. The conditions proposed were these, "That the Biobio should serve as a barrier to both nations, so that neither should be permitted to pass it with an army; that all deserters, in future, should be mutually returned; and that the missionaries should be permitted to preach the doctrines of Christianity in the Araucanian territories." After the execution of the required preliminaries, and when the treaty was on the point of being finally concluded, the whole proceedings were completely overturned by the obstinate bigotry or the interested opposition of the Spanish officers. One of the Toqui's wives, a Spanish lady, whose detention in that capacity had been compulsory, seizing the occasion of her husband's absence, fled to the governor with two small children. Ancanamon vainly demanded their restoration: his claim was rejected by a majority of officers. He then claimed his two infant daughters, for whom he bore the fondest attachment; but of these also the eldest was denied him, on the plea that she had been converted to Christianity, and might be in danger, in a pagan country, of receding from the faith. In the mean time the Ulmen of Illicura had, from motives of gratitude to Valdivia, engaged to facilitate the negotiation, and at the same time received some missionaries into his province. The exasperated Toqui, who had now abandoned all desire of peace, no sooner was informed of this proceeding, than he hastened with a party of two hundred horse to Illicura, and immediately slew the missionaries with their protector. All attempts to revive the negotiation were fruitless.

Hostilities renewed.

Thus frivolously was rekindled a war, which, in its course, had already drained Araucania of its bravest inhabitants, and drenched its fields with the best blood of the enemy. Ancanamon poured out his indignant vengeance on the Spanish provinces, and some severe engagements followed. But the levity of the Spaniards received its full measure of retribution, during the dictatorships of Lientur and Putapichion. The ardent genius and enterprising spirit of Lientur carried every thing before him. His expeditions were a succession of triumphs to his country, and of discomfiture and humiliation to the Spaniards: he retired with glory in his old age, regarded even by his enemies as the darling of fortune. He was succeeded by Putapichion, a leader possessed of talents scarcely inferior, though less uniformly triumphant, but whose laurels were shamefully polluted, by reviving, happily but in one instance, the cruel ceremony of the pruloncon or dance of the dead.[§] He fell gloriously, in a bloody engagement with the Spanish governor Don Francisco Laso, and in the moment of success; but his soldiers, intent only to remove the body of their leader, permitted the enemy to rally his dismayed battalions, and lost a victory which their valour had in part achieved. The death of Putapichion threw a superiority on the side of the Spaniards. His successors in the Toquiate, with equal ardour to annoy the enemy, were deficient in those qualities, which could alone secure its accomplishment. Their efforts, though not always ineffectual, seem in general to have been the result rather of temerity than of skill. They have the just praise, however, of having been sincere in the great cause of their country, and their sincerity was sealed with their blood. In the course of a very few years Araucania was deprived of five successive Toquis, and, during that period, was frequently exposed to severe ravages from the governor.

---

[*] The capture of this city was greatly protracted by the active intrepidity of Ines Aguelera, who, after losing her husband and brother, conducted the defence in person. She escaped with part of the inhabitants; and the king rewarded her valour by an annual pension of two thousand dollars.

[†] According to an account addressed to the court of Chili, (1774) by Don Ignatius Pinuer, the Spanish garrison of Osorno retired to a peninsula formed by a lake at the south foot of the Andes, where they built and fortified a city, and were known to the Indians by the name of Alcahuncas. Of this establishment the officers are said to have become the tyrants, and used the strictest precautions to prevent intelligence of its existence being carried to any of the Spanish settlements; and in this they were actively seconded by the surrounding Indians.

[‡] "The garrisons," says the Abbé Molina, "were compelled to subsist on the most loathsome food; and a piece of boiled leather was considered as a sumptuous repast for the voluptuous inhabitants of Villarica and Osorno."

[§] It was the custom of this barbarous festival to sacrifice one of the captives to the manes of the soldiers slain in battle. A minute description of the ceremony will be found in the article ARAUCANIA.

Expeditions of the Dutch and English against Chili.

The Spanish settlements were again threatened by the Dutch and English. The first arrived upon the coast in 1638, when a storm frustrated their enterprise, by the dispersion of their little squadron. Some years after, the English fleet, on its way to Chili, under Sir John Narborough, was lost in the straits of Magellan.

A peace concluded between the Araucanians and Spaniards.

Laso, like some of his predecessors, had engaged his promise to terminate the war with the Araucanians, but notwithstanding his utmost endeavours, and the vigorous ability with which these were exerted, they still obstinately maintained their freedom; and he was at length reduced to the necessity of soliciting reinforcements. Instead of these, however, the court of Spain sent out the Marquis de Baydes to displace him from the command. De Baydes, immediately on assuming the government, (1643,) opened a conference with the Toqui Lincopichion; and the two chiefs, entertaining similar views, a peace was concluded on the 6th of January, the following year, upon the terms proposed to Ancanamon, but with this further requisition, that the Araucanians should not permit the landing of any strangers upon their coast, nor furnish supplies to any foreign nation whatever. This prudent stipulation proved shortly of the highest importance to the Spaniards.

The Dutch frustrated in their last attempt to dispossess the Spaniards.

In 1643, the Dutch, after the reduction of Brasil, renewed their attempts upon Chili; but this their last effort, though apparently more formidable and better concerted, was not more successful than the two former. They possessed themselves of the deserted harbour of Valdivia; and the Araucanians were in vain solicited with the most pressing invitations to break with their ancient enemy. Not only, however, did they remain faithful to their engagement, but readily united with a Spanish army to expel the strangers. Upon intelligence of their approach, the Dutch, greatly oppressed for want of provisions, found themselves once more compelled to abandon the enterprise.

Rupture with the Araucanians.

In 1655, hostilities were excited afresh during the government of Don Antonio Acugna; but from what cause, or which party was the aggressor, we are not informed. The Toqui Clentaru, in his first enterprize, had the glory of annihilating a Spanish army. He then cleared the country of some remaining fortresses, crossed the Biobio, and after defeating the governor, overturned the forts of St Christopher and the Eustacia del Rey, and burned the city of Chillan. Don Francisco Meneses brought the war to a termination in 1665, by a peace which lasted forty-eight years. During this period little occurred deserving particular notice. A slight rebellion took place among the inhabitants of Chiloe; which, however, was quickly suppressed by the prudent exertions of Don Pedro Molina. During the war of succession in 1707, the external commerce of Chili fell into the hands of Frenchmen, and remained wholly under their management till 1717. Many of them settled in the country, and have left numerous descendants.

The war of 1723 menaced the Spaniards in its commencement with total expulsion from Chili. It appears to have been excited by some encroachments on their part, and by the insolent aggressions of those persons styled *Captains of the Friends*, (Spanish officers placed in Chili for the ostensible purpose of protecting missionaries). The assumption of powers which did not originally belong to them was deeply resented, and soon stirred to a flame the watchful jealousy of the Araucanians. Villumilla was elected Toqui in 1722. His first aim was to engage the co-operation of all the Chilians, that by one sudden and overwhelming effort he might sweep the Spaniards from every province of the country. But though his measures to this effect were taken with vigour, secrecy, and precision, its accomplishment was entirely frustrated, by the inaction of the conquered Chilians. The long and rigid despotism which had been exercised over them with such barbarity by the Spaniards, had not only repressed the population, once numerous and flourishing, but reduced it to a spiritless remnant. The small number therefore, and the broken spirit of these injured and degraded beings, should perhaps exculpate them from the charge of cowardice. On the day appointed, the signal fires served only to remind them of ancient freedom, without exciting a single effort to regain it. Villumilla, thus disappointed of extensive co-operation, though he was not deterred from attacking the enemy, accomplished nothing of importance. He succeeded in taking several fortresses; but the governor, Don Gabriel Cano, who had entered Araucania with an army of 5000 men, not choosing to attack him, the war was reduced to skirmishes, and soon afterwards terminated by the peace of Negrete.

The interval of tranquillity was occupied by a succession of governors, in forming new establishments, and peopling them with great numbers of their countrymen, at that time scattered over the provinces. An attempt to extend the same policy, with very different views, to Araucania, produced a rupture with that vigilant people, who, regarding cities as the emblems of servitude, and with extreme aversion, could not be persuaded to adopt a measure which might one day prove instrumental in subverting their liberties. The subsequent war, however, of which we have no particular account, compelled the Spaniards to forbear even such indirect methods of reducing a warlike nation, resolved to remain independent, or to perish with its freedom. The peace which followed in 1773, was a confirmation of the treaties of Quillin and Negrete. During the negotiations which, at the desire of the Toqui Curignancu, were held in St Jago, a demand, rather unexpected, was made from the same authority. It was required, that henceforth the Araucanians should be permitted to keep a minister resident in that city. This also, notwithstanding the opposition of his officers, the governor thought proper to concede, and every obstacle being removed, the terms were adjusted and ratified on the bases of the preceding treaties.

Since their last expulsion from Araucania the Spaniards have prudently abstained from any further attempts to regain their possessions in that warlike province; the preservation of which had already been attended with so much hazard and bloodshed. In 1792 the colony was in a flourishing state under Don Ambrosio Higgins, a native of Ireland, who increased the number of its cities, extended its commerce and fisheries, encouraged its agriculture, and by the whole of his able and useful admini-

History.

stration became the object of universal regard. Since that period no intelligence of interest or importance has been received from Chili, except the general fact, that with the other Spanish colonies in America, it has withdrawn its allegiance from the present government at Cadiz, while it acknowledges Ferdinaud VII.

Part II. STATISTICAL ACCOUNT OF CHILI.

Statistics.

General geography.

Chili is bounded on the north by Peru, on the south by the land of Magellan, on the west by the Pacific Ocean, and on the east by Tucoman Cujo and Patagonia. The natural limits of Chili on the land side are the Andes or Cordillera and the desert of Atacama. It is to be remarked, however, that not only the western vallies of the Andes, but also the eastern, which have been occupied from time immemorial by Chilian colonies, make an integral part of the country. In length it has been computed at 1260 geographical miles. Its greatest breadth, which is near the Archipelago of Chiloe, is about 300 miles. Between the 24th and 32d degrees of latitude, in a direct line from the coast to the mountains, it measures about 210, and its narrowest part from the 32d to the 37th, not more than 120 miles. It contains a surface of 378,000 square miles.

Origin of the name.

Among the various whimsical derivations of the name of Chili, that suggested by the inhabitants is, perhaps, the least absurd. They derive it from the note or cry of one of their birds, which in its utterance somewhat resembles the word Chili; and "it is not improbable," says Molina, "that the first tribes who settled there, considered this note as a good omen, and named the country accordingly."

Aspect and natural divisions.

Chili presents a plain, gradually rising in elevation as it recedes from the coast and approaches the Cordillera. From this sloping conformation it is fertilized and beautified by innumerable rivers, which having their source in the mountains, cross the country from east to west, and discharge themselves into the Pacific Ocean. The natural divisions of Chili are three in number; Chili Proper, the country of the Chilian Andes, and the Islands. *Chili Proper*, comprehended between the Andes and the sea, and measuring in breadth at least 120 miles, has been divided into two equal portions, viz. the Maritime and Midland. Three chains of mountains, parallel to the Andes, intersect the Maritime country. The Midland portion is almost an uniform plain, interspersed only with a few solitary hills. That portion of the *Andes* which belongs to Chili, is about 120 miles in breadth. It contains a vast number of contiguous and very lofty mountains, and in its various scenery exhibits often the most striking features of the grand, the picturesque, and the beautiful. The *Islands* that belong to Chili are the Coquembanes, Mugillon, Totoral, and Pajaro, which remain desert; Carama, which is a mere rock and scarcely worth notice; the two islands of Juan Fernandez, Isola di Terra (the shore islands), and Masafuera (the more distant), both of which are beautiful and inviting, but the first only (Isola di Terra), which is the largest, is inhabited by a few Spaniards; Quirequina and Talca, or Santa Maria near Conception; Mocha, on the coast of Araucania, which is more than 60 miles in circumference, handsome, and fertile, but deserted by the Spaniards; the Archipelago of Chiloe, which, with that of the Chones dependent upon it, comprehends eighty-two islands, at present occupied by Spaniards and Indians. Chiloe, the largest of these, is in length about 150 miles, and gives its name to the Archipelago. All the above islands, except those of Juan Fernandez, are situated near the coast.

Chili Proper.

The Andes.

Islands.

Political divisions.

Chili may be divided politically into two parts; the conquered portion, in possession of the Spaniards, and the Indian part, which still maintains its independence. Spanish Chili extends from the 24th to the 37th degree of south latitude, and is divided into thirteen provinces, which we here subjoin, beginning from the north, with a short statement of their extent, productions, and capitals. *Copiapo*, stretching from the Andes to the sea, is in length 100 leagues by 70 in breadth. Its northern part is chiefly inhabited by hunters of the vicugna. This province contains mines of lead and silver, and abounds in gold, lapis lazuli, and fossile salt. Copiapo, the capital, is situated on a river of the same name, in 27° 10′ south latitude, and in west longitude 71° 5′ 15″. Copiapo, extending also from the Andes to the sea, is 70 leagues from north to south, and 45 from east to west. The soil is fertile, producing abundance of grapes, olives, and other fruit, both native and European. It is rich in gold, copper, and iron. Its capital, Coquimbo, or La Serena, stands in south latitude 29° 54′ 40″; west longitude 71° 19′ 15″. *Quillota*, lying on the sea-coast, is 25 leagues in length, and 21 in breadth. This province is one of the most populous in Chili, and is particularly abundant in gold. The capital, named Quillota, or San Martin, is in south latitude 32° 42′, and west longitude 71°. *Aconcagua*, is an inland province, comprehending part of the Andes; 75 leagues in length, and the same in breadth. It is fertile in grain and fruit; produces excellent copper, and contains the rich silver mines of Uspalata. The capital, Aconcagua, or San Filipe, is situated in lat. 32° 18′, and long 69° 55′. *Melipilla*, on the sea-coast, measures 11 leagues from north to south, and 23 from east to west. It is a beautiful and fertile province, abounding in wine and grain. Melipilla, or San Joseph de Lagrano, the capital, is finely situated on the river Maypo, in lat. 33° 36′, long. 70° 42′. *Santiago*, near the Andes, is a small province, measuring only 11 leagues from north to south, and 20 from east to west; it is, however, extremely fertile, and abounds in grain, wine, and excellent fruits, especially peaches. Capital, St Jago, in lat. 33° 16′, long. 69° 48′. *Rancagua*, extending from the Andes to the sea, is 40 leagues from east to west, and 13 from north to south. It is fruitful in grain, and has a rich mine of gold in the vicinity of Alque. The capital, Santa Croce de Trianna, or Rancagua, lies in lat. 34° 18′, long. 70° 16′. *Calchagua*, reaching from the Andes to the sea, is from east to west 43 leagues, from north to south 15. This is a rich province, abounding in grain, wine, fruits, and gold. San Fernando, the capital, is in lat. 34° 36′, long. 70° 34′. *Maulé*, extending from the Andes to the sea, is 44 miles from north to south, and from east to west 48. It abounds in grain, wine, fruits, cattle, fish, salt, and gold. Several noble families, whose finances had been much reduced, having retired to this province, it has, from that circumstance, received the appellation of the Bankrupt Colony. It contains many villages of native Chilese, and one in particular, *Laro*, inhabited by Promaucians, and governed by a native chief or Ulmen. Capital Talca, or St Augustin, in south lat. 35° 18′, west long. 70° 48′. *Itata*, on the coast, 11 leagues from north to south, and 23 from east to west. It affords the best wine in Chili, known by the name of Conception wine, from its being produced on

Spanish Chili, with a description of its provinces.

lands belonging to inhabitants of that city. The capital, Coulemu, or Nombre de Jesus, is situated on the Rio Jesus, in south lat. 35° 58′, west long. 72° 38′. *Chillan*, an inland province, near the Andes, 12 leagues from north to south, and 25 from east to west. Its plains being considerably elevated, afford excellent pasture for sheep, whose wool is reckoned of a superior quality. The capital is Chillan, or San Bartholomew, in south lat. 35° 54′, west long. 71° 30′. *Puchacay*, on the sea-coast, 12 leagues from north to south, and 25 from east to west. The soil of this province is fertile, and the climate always temperate. It produces the largest strawberries in Chili, and abounds in gold. Conception, in south lat. 36° 49′ 10″, west long. 73° 5′, is the principal city, though the corregidor resides in Gualqui. *Huilquilemu*, more generally named Estanzia del Rey, lies near the Andes, and is 12 leagues from north to south, and 25 from east to west. This province has mines of gold, and produces excellent wine, resembling Muscadel. The capital is Huilquilemu. *Valdivia*, now used only as a military station, is completely separate from the other Spanish provinces, and encompassed by the territories of the Araucanians. The capital, Valdivia, is situated at the bottom of a secure bay, whose entrance is commanded by the island Manzera.

All the above provinces, excepting Valdivia, were anciently possessed by the Copiapins, Coquimbanes, Quillotanes, Mapochinians, Promaucians, Cures, Cauques, and Pencons. But most of these once flourishing tribes are now extinct, and the few that survive have been wasted to a miserable remnant, by the oppressive tyranny of the Spaniards.

The independent provinces. That portion of Chili which still maintains its independence, lies between the 36th and 41st degrees of south latitude, extending from the Biobio to the Archipelago of Chiloe. It is at present occupied by three independent nations, the Araucanians, the Cunches, and the Huilliches. *Araucania*, extending from the Biobio to the river Callacallas, contains the finest plains of Chili. It is in length 186 geographical miles. Its original breadth was 300, but in the 17th century it was augmented to 420, by the junction of the Puelches, who inhabit the western side of the Andes. The united territory is computed at 78,120 square miles. It is divided into four parallel principalities, termed *Uthalmapu*, which are distinguished by the following descriptive appellations: Lauquenmapu, or the maritime country; Lelbunmapu, or the plain country; Inapiremapu, or the country at the foot of the Andes; and Piremapu, or the country on the Andes. These are each of them divided into five provinces, which are again subdivided into nine districts.* Between the river Callacallas, and the Archipelago of Chiloe, is comprehended the territories of the Cunches and Huilliches, who are both allies of the Araucanians. The Cunches occupy the part extending along the coast; the Huilliches inhabit all the plains to the eastward, between the Cunches and the main ridge of the Andes.

Mountains. The highest of the Chilian Andes are, the Manflos, in south lat. 28° 45′; the Tupungato, in 33° 24′; the Descabezado, in 35°; the Blanquillo, in 35° 4′; the Longavi in 35° 30′; the Chillan, in 36°; and the Corcobado, in 43°, all of which are said to be more than 20,000 feet above the level of the sea. The most remarkable of these is the Descabezado, whose summit presents a plain of more than six miles square, having in the middle a very deep lake. This lake is supposed to have been at one time the crater of a volcano. In height, it is probably not inferior to the celebrated Chimborazo of Quito. Between the 24th and 33d degrees of south latitude, the Andes are wholly desert. From this to the 45th, they are occupied by Chilian colonies, under the general name of Patagonians, but whose different tribes are likewise known by the separate appellations of Chiquillans, Pehuenches, Puelches, and Huilliches.

Rivers. Chili is watered by a vast number of rivers, which proceeding westward from the Andes, discharge themselves, by fifty-two mouths, into the Pacific Ocean. The principal of these are, the Maule, the Biobio which is two miles in breadth, the Cauten, the Tolten, the Valdivia or Callacallas, the Chaivin, the Riobueno, and the Sinfondo, which, with some others, are navigable for a considerable extent to ships of the line. Their course is very rapid till they reach the maritime Mountains, where it is retarded by the nature of the ground. They swell to their greatest height about the end of September, when it has been remarked that some of them rise most in the morning, others at mid-day, and others towards evening. At no time, however, do they so much overflow their banks as to lay the adjacent plains under water.

Lakes. The lakes of Chili are of two kinds, the salt and fresh water lakes. Of the former are the lakes of Bucalemu, Caguil, and Bojeruca, situated in the marshes of the Spanish provinces. Those of fresh water belong to the inland provinces; they are the Redaguel, the Aculeu, and the Taguatagua; also the Lauquen and Nahuelguapi, in Araucania, the first of which has a beautiful cone-shaped hill rising from its centre, and is the source of the river Talton. The Nahuelguapi is 80 miles in circumference, has a pleasant island, and gives rise to a river of the same name, which falls into the Patagonian sea.

Towns. The towns of Chili are built in the finest parts of the country, but not always placed so advantageously as they might have been, for the purposes of commerce. The streets are about 40 feet wide, intersecting each other at right angles, and forming so many squares. The houses in general are built of mud or clay hardened in the sun, having but one storey, with a garden attached to each of them; many, however, of more recent construction, are composed of brick or stone, and furnished with upper stories. In our sketch of the provinces, we have already mentioned the principal cities; but we shall here notice more particularly some of the most remarkable. *St Jago*, the capital of the Spanish provinces, was founded in 1541, by Pedro de Valdivia, and is finely situated on the left bank of the river Mapocho, in a beautiful plain 24 leagues in extent; it stands 90 leagues from the sea, and 20 from the main ridge of the Andes; the river is employed in watering its numerous gardens, and is conveyed through the streets by means of conduits. The principal suburbs lie on the opposite bank of the river, and a fine bridge connects them with the city. The houses of St Jago, though very low, and in general but of one story, are both handsome and convenient. The grand Piazza, near the middle of the city, is 150 feet square, having an elegant bronze fountain in its centre. The inhabitants, in 1770, were computed at 46,000. *Conception*, or Penco, was founded by Valdivia, in 1550; but being twice overwhelmed by an earthquake, accompanied by an inundation of

* The names of these provinces and districts are given in the article ARAUCANIA.

Statistics.

the sea, its first situation was abandoned for one more secure, and the city was rebuilt (1764) about a league from the shore. It contains about 13,000 inhabitants. The bay of Conception is the largest on the coast of Chili, and has two entrances formed by the Island Quiriquina at its mouth, the east of which is the safest and most frequented. Its best port is that of Talcaguana. *Coquimbo*, or La Serena, founded by Valdivia in 1544, presents a beautiful appearance, the wide spaces between its squares being entirely occupied by gardens; the houses are built of mud, covered with leaves. It is a large town, but not proportionably inhabited. *Valparaiso*, the principal sea-port in Chili, from whence is transacted all the trade with Peru, is large, populous, and flourishing. It lies about three miles from the port; but there is another town called Almendral, close upon the harbour, which is the residence of those employed about the shipping. The harbour is capacious, and sufficient to contain large vessels up to the shore. Valparaiso has a military governor, or corregidor, nominated by the king.

Forts.

The principal forts have been erected on the southern frontiers, to repress the incursions of the Araucanians. On the north side of the Biobio, are the forts of Jumbel. Tucapel, Santa Barbara, and Puren. To the south of the same river is the fort of Arauco, with those of Colcura, San Pedro, Santa Joanna, Nascimento, and Angeles.

The Araucanians have neither walled cities, nor permanent fortifications of any kind; but regarding these as emblems of slavery and dependence, they reside in scattered hamlets, which are commonly situated on the banks of rivers, or on plains that possess the convenience of an easy irrigation.

Soil.

The inland parts of Chili are the most fertile, and the fertility increases in proportion to the distance from the sea. The vallies of the Andes are superior to the middle districts, and these to the maritime. In the maritime districts the soil is brown inclining to red, brittle, and clayed, and contains marl mixed with marine substances. In the interior, and in the vallies of the Andes, it is brittle, and of a yellowish black colour. It every where possesses an extraordinary warmth, and brings to perfect maturity those tropical fruits which are natives only of the torrid zone. The inexhaustible sources of fertility in this delightful country, renders unnecessary the use of artificial manures, and experience has taught the husbandmen of Chili their superfluity, if not injury. The fermentation and putrefaction of manure is supposed to engender or multiply certain worms destructive to grain in the blade. From these Chili is entirely exempted; and it is alleged as a known fact, that the lands of St Jago, though they have been constantly cultivated for a period of near two centuries and a half, without receiving any artificial manure, have suffered no diminution in their amazing produce. The soil of Chili, by a very moderate calculation, yields, at an average, 65 for one in the middle districts, and 45 in the maritime. There are, indeed, lands which produce 120, and 160 for one; and, according to some authors, there have been frequent instances of 300 fold; but this extraordinary increase has not been confirmed by later and more authentic information.

Climate.

The climate is mild, equable, and salubrious, and not inferior to any in the new world. The transition from heat to cold is moderate, and their extremes equally unknown. The air is so much cooled in summer by certain winds from the Andes, distinct from the east winds, that in the shade no one is even incommoded with perspiration. In the interior where the heat is greatest, Reaumur's thermometer seldom exceeds 45°, and in winter it very rarely sinks below the freezing point. Chili enjoys a constant succession of fine weather from the beginning of spring till autumn. The rainy season commences in April, and continues to the end of August. The southern provinces have much more of it than those in the centre, while in the northern provinces of Coquimbo and Copiapo it rains very seldom. In these provinces, however, and throughout the country, the dews fall in such abundance, as in a great measure to supply the want of rain. Snow, except on the Andes, is very uncommon. On the coast it is entirely unknown, and though it sometimes falls in the middle districts, it is often melted before reaching the ground, and is seldom known to lie for the space of a day. On the Andes, however, from April to November, it falls in prodigious quantities, and renders the passes for the greater part of the year altogether impracticable.

Winds.

The winds in Chili are considered as infallible indications of weather, and serve the inhabitants for a barometer. The southerly winds proceeding directly from the Antarctic pole, are cold, attended with fair weather; the northerly winds, on the contrary, are hot and humid, and usually bring rain. In the provinces of Cujo and Tucoman, they are more suffocating than the Siroc in Italy; but in crossing the snowy summits of the Andes to Chili, their noxious properties are in a great measure removed or qualified. The south wind prevails while the sun is in the southern hemisphere. It begins to relax about noon, and is then supplanted for two or three hours by a fresh breeze from the sea, which, from the regularity of its returns, is called the twelve o'clock breeze. The south wind returns in the afternoon, and at midnight is once more succeeded by the western breeze. The east wind is seldom felt in Chili; and there exists but one instance of a hurricane.

Meteors.

Meteors, especially shooting stars and balls of fire proceeding from the Andes to the sea, are very frequent in Chili. The aurora australis seldom appear. One of the largest of these phenomena happened in 1640, and remained visible from February to April.

Volcanoes

Among the vast number of volcanoes in the Cordillera, there are fourteen in a state of perpetual combustion, all of which belong to Chili, and are situated near the middle of the Chilian range: the lava and ashes discharged from them never fall beyond the limits of the Andes. Only two volcanoes are found among the maritime and midland mountains; one at the mouth of the river Rapel, which is small, and emits at intervals only a little smoke; the other is the great volcano of Villarica, distinguishable at the distance of 150 miles, and said to be connected by its base with the Andes. It continues burning without intermission, but its eruptions have seldom been violent. The base is covered with forests, and its sides with a lively verdure. The most remarkable eruption of the Chilian volcanoes was that of Peteroa, in the 3d of December 1760, when the volcanic matter opened for itself a new crater, and a mountain in the vicinity suffered a disruption to the extent of several miles. A large portion of the mountain fell into the Lontue, and having filled its bed, a lake which still remains was thus formed by the overflowing of the river.

Earthquakes.

Chili, so highly favoured in other respects, is rendered, by its quantity of inflammable matter, extremely subject to earthquakes. There are, however, two of its provinces which would seem to be almost totally exempted from their influence. It is a remarkable fact, that while other parts of the country have been violently agitated, the shock, if felt at all, was but slightly perceptible in Copiapo and Coquimbo: this some have attributed to the supposed existence of certain large subterraneous caverns intersecting these provinces, which, by affording vent to the inflamed substances, may thus suddenly arrest the progress of the convulsion. It is a very great alleviation of this tremendous scourge, that its approach is invariably announced by certain hollow sounds, the effect of a vibratory motion in the atmosphere, which give the inhabitants warning to quit their houses, and take refuge in the streets, courts, and gardens. Happily the streets are of such a breadth as to afford a safe retreat, though the houses on each side should fall to the ground. Only five considerable earthquakes have occurred in Chili since the arrival of the Spaniards to the year 1782, a period comprehending 244 years. The first in 1520, and the second in 1645, were attended with no very serious injury. The third, which took place on the 15th of March 1657, overturned a great part of St Jago. The fourth, on the 18th of June 1730, produced an inundation of the sea, which beat down the walls of Conception. The fifth, on the 26th of May 1751, was immediately preceded by slight shocks, and the appearance of a ball of fire darting from the Andes to the sea. It completely overwhelmed Conception, and destroyed all the fortresses and villages between the 34th and 40th degrees of latitude. Its course was from north to south, and slight tremblings, with intervals of fifteen and twenty minutes, were experienced for the space of a month after the earthquake.

Physical organization. Various marine substances are to be found almost in every part of Chili, and on the tops even of its loftiest mountains. In the main ridge of the Andes, the external form of the mountains is that of a pyramid, covered in some instances with conical elevations. Their internal structure consists of large primitive rocks of quartz, differing very little in general configuration. The maritime and midland mountains, together with the lateral chains of the Andes, are of secondary formation, and, in their structure, differ essentially from those of the main ridge, which are primitive: they rise abruptly from the base; their summits also are more rounded; and their strata, which are horizontal and of unequal thickness, abound with marine productions, and contain the impressions of animals and vegetables. These secondary mountains are in general stratified, containing a large variety of minerals, and covered with a deep soil and plentiful vegetation. Some of them, however, are homogeneous, all of which are barren, and exhibit on their surface only a few languid shrubs. Of the homogeneous mountains, some are composed entirely of shells, others of gypsum, of granite, of quartz, of freestone, of basalts, of lava, and some are calcareous. The organization of the vallies is similar to that of the stratified mountains. **Caverns.** The maritime mountains present on their western declivities many curious excavations or grottos, all beautifully hung with shells and spar. These caverns are also very numerous in the Andes. The most remarkable of them is that near the source of the river Longavi, which, immediately before sun-rise, exhibits to the spectator a very unexpected phenomenon; the rays, penetrating the cavern by some hidden aperture, reach his eye before they have yet tinged the summits of the Cordillera. In the same range also may be seen, a large mountain of gypsum, perforated quite through by the river Mendoza. It is called the Inca's bridge; and has its interior surface finely ornamented with large clusters of stalactites. Among these natural curiosities, we must notice an immense block of white marble completely insulated, and measuring in height 75 French feet, 224 in length, and 54 in breadth. It stands on the left bank of the river Maule, about four hundred paces from its mouth, and, from its appearance, has been called the church. It contains a vast arching cavity, furnished with three semicircular apertures. At one of these the sea enters, and the cavity is thus frequently visited by sea wolves.

Mineralogy. Chili contains almost every kind of metal. It has mines of gold, silver, copper, lead, iron, and tin. There has been lately discovered also in the mountains of Copiapo, the ore of a new metal unknown to the miners, but which, from their description, is supposed to be platina. **Metals.** *Gold* is particularly abundant, and found in all parts of the country; in every precipice and mountain, as well as in the sand of its numerous rivers. The principal gold mines are those of Copiapo, Guasco, Coquimbo, Petorca, Ligua, Tiltil, Putaendo, Caen, Alhue, Chibato, and Huilli-Patagua. The three last are of recent discovery, the others have been wrought since the conquest. The metal dug in the two provinces of Copiapo and Guasco, has, from its superior quality, received the appellation of *oro capote*. Though in Chili gold is found united with almost every sort of stone and earth, its usual matrix is a red clay stone, extremely brittle. The course of its veins is commonly from south to north. In some places, however, they descend almost vertically, and, in others, take a circular direction. Independent of the mines, great quantities of gold are obtained by washing the sands of rivers, which sometimes yield solid lumps of a pound in weight. This operation is generally performed by individuals of the poorer class, who are not able to afford the expence of mining. The gold of Chili is in general from 22 to 23½ carats. There has been no correct estimate of the quantity annually collected. That which pays the duty or fifth part to the king, amounts to about 900.000 pounds sterling; but there is also a very great proportion smuggled. This has been computed at more than a third part of the whole product. The ores of *silver* are confined to particular districts, and found only in the most elevated regions of the Andes. The most productive are those of St Jago, Coquimbo, Copiapo, and Aconcagua. In the last province is the mine of Aspalata, the largest and richest of the silver mines in Chili. Its precise extent is unknown, but it has been traced running in a northerly direction to the distance of thirty leagues, and is imagined by some to be a ramification of the mine of Potosi. It yields a sort of black ore, which is greatly esteemed. Of this ore there are three varieties, but the best of them is that called *piombo ronco*, which is the most readily separated. *Copper* is plentiful, and, like gold, is confined to no particular district. The best mines of it, however, are situated between the 24th and 36th degrees of latitude. The mine of Payen, which was formerly the most productive in Chili, has been long abandoned, on account of the hostility of the Puelches, in whose territories it was discovered. It is said to have produced pieces of pure metal, from fifty to a hundred pounds in weight, of a colour resembling pinchbeck, and containing, in most instances, more than an equal portion of gold. A mine, not inferior to this, has been lately opened at Curico. The copper of Chili is found variously mineralized; but, in general, it appears in combination, with a greater or less proportion of gold. There are only two kinds of it at present wrought by the inhabitants: these are the malleable copper, and the grey or bell-metal, which, from its composition, colour, and brittleness, may be regarded as a sort of native bronze. The others, though rich in metal, are considered as of no value, from the difficulty attending their separation. Of the malleable copper, those mines only are wrought, whose ore gives half its weight in refined metal; and there are at present open between the towns of Copiapo and Coquimbo more than a thousand such mines. Near the river Laxa in Huilquilemu, are hills which afford a beautiful native brass or copper in natural combination with zinc: it receives the name of Laxa copper. The mines of *tin* and *lead* are both equally neglected. Only so much of the lead is wrought, as may be required for the melting of silver and domestic purposes: small quantities of gold and silver are found in conjunction with it. Tin never appears in a continued vein, but is contained in a black stone of various form and dimensions. It is found also in coloured crystals. *Iron* also is very abundant, but the mining of it is prohibited in favour of the traders in that metal from Spain. Coquimbo and Copiapo abound in mines of it. **Semi-metals.** *Semimetals* of all kinds are found either separate, or mineralized with metallic ores. Antimony and quicksilver are the only two in any request; the first employed in refining the precious metals, the other being a royal monopoly. Virgin mercury is found in the province of Coquimbo, but it commonly appears in the form of Cinnabar. **Mines.** With respect to mines in general, the permission of government is to be obtained before working any newly discovered vein. An inspector is then appointed, who portions out the mine into three equal shares; one for the king, another for the proprietor of the land, and a third for the discoverer of the vein. If it prove rich, a village is quickly formed in the vicinity, by the immense number of persons that receive employment. An alcade or superintendant of the labourers is then appointed by the governor of the province. **Pyrites.** *Pyrites* are very numerous, but we shall notice only one species, which is the auriferous, found in Quillota, called the *Inca's stone.* It is cubical, and distinguished from all others by emitting but few sparks with the steel. **Bitumens.** The *bitumens*, are asphaltum, petroleum, pit-coal in great abundance, and several kinds of jet. Ambergris is often thrown out by the sea on the coast of Araucania and Chiloe. On the shores, also, are occasionally found pieces of yellow amber. Two small mountains of Copiapo consist almost entirely of a beautiful crystallized sulphur, so pure, that it does not want refining. *Salts* of these, are the blue, green, white, and mixed vitriol; sal ammoniac, with an excellent fossil salt, in the form of transparent cubes, crystallized and variously coloured. Several mountains of it occur in the Andes, west of Copiapo and Coquimbo; and it is used by all the inhabitants in the vicinity. A semi-crystallized aluminous stone, employed in the process of dyeing, and similar to that of Talca, is obtained from the Andes.

Stones. *Stones.* Of the siliceous kind, there are *rubies*, *sapphires*, *lapis lazuli*, and various sorts of *jasper*. At Coquimbo was found a beautiful *emerald*, and a very large *topaz* in the province of St Jago. *Amethysts* occur almost at every step in the crevices of rocks; and near Talca, there is a small hill consisting almost entirely of that stone. There are coloured *crystals* resembling most of the precious stones; and the Andes produce pieces of rock crystal, large enough to form columns six feet in height. These mountains abound also in *breccias*, *porphyries*, and *granite*. Among the calcarious sort, we may notice marbles of all colours, many of them finely striped and variegated. *Gypsum*, of which there are quarries in a semi-calcined state, slightly tinged with blue, and employed as a plaster for walls. There is a beautiful hexagonal *spar* found in the gold mines of Quillota, perfectly transparent, and striped with golden filaments. In the Andes are quarries of *alabaster*, with a sort of pellucid *selenite*, used for glass in the churches of St Jago. Of the *argillaceous*, the most remarkable are *asbestos* and the membranaceous *mica*, which supplies the place of glass, and being less fragile and more pliable, is by many preferred to that substance. **Concretions.** The *concretions* are *pumice-stone*, which forms the substance of several mountains; *turquoils* of a blue colour, which are found in the hills of Copiapo, and have generally been considered as a precious stone, but are nothing more than the teeth or bones of animals in a state of petrifaction; and petrified wood, which occurs in every part of the country. The Chilian willow is particularly susceptible of this change, and, in order to accomplish it, it is only necessary to place it for a short time under a moist and sandy soil. **Earths.** Chili contains *earths* of almost every description, the argillaceous, the calcareous, the sandy, and the mineral. Of the argillaceous, Molina has discovered five new species. Of these, the two most remarkable are the *argilla buccarina*, which is of a brown colour, spotted with yellow, pleasant to the smell, and even when manufactured into cups, &c. gives an agreeable flavour to the water drunk from them; and the *argilla rovia*, which supplies an excellent black, and is employed in dyeing wool. *Sand* abounds in the rivers of Chili; but is never found in such quantity on the plains as to prove injurious to vegetation.

Mineral waters. The most celebrated mineral springs of Chili are those of Peldehues and Cauquenes, both Spanish settlements. The Peldehues contains both a hot spring and a cold one. The hot spring is clear, inodorous, oily to the touch, and foams like soap, abounding in mineral alkali, and containing a small quantity of fixed air. Its specific gravity exceeds that of common distilled water only by two degrees. The cold spring is iron and vitriolic. The waters of both springs being distant from each other only about eighty feet, are united by means of canals, and form a tepid bath. This junction occasions a deposition of Glauber's salt, and of a yellowish ochre. The springs of the Cauquenes, situated near the source of the river Caciapol, in one of the vallies of the Andes, are extremely numerous both hot and cold, and possess very different qualities. Some are acidulated, and contain iron; others are alkalescent, or vitriolic; and others gaseous. There are a great many salt springs in the provinces of Copiapo and Coquimbo; and, in the former province, is the river Salado, which affords an excellent salt, so pure, that it may be used without any preparation.

VEGETABLE PRODUCTIONS. Chili is one of those countries where vegetable and mineral productions are found in equal abundance, and affords an exception to the general maxim, that mineral countries are deficient in vegetation. The plants of Chili are, on the contrary, every where profuse, vigorous and luxuriant.

Trees. Its plains, vallies, and mountains, abound with trees of unfading verdure and delightful fragrance. Of 97 species already discovered, only 13 shed their leaves. The *pellinos*, a species of oak, the pine, the cypress, and the red and white cedar, are found in a natural state in the valleys of the Andes. The *red cedar* is remarkable for its enormous dimensions, particularly in the Archipelago of Chiloe, where a single tree will sometimes yield 700 boards, each 20 feet long. In other parts of Chili are found the mulberry, the chirimoya, and the tamarind. Besides these we may notice particularly the *theige*, or Chilian willow, which yields manna, and whose bark is used by the natives as a preservative against fevers; the *molle*, of two kinds, the berries of which afford a red wine, well flavoured, but heating; the *Peruvian taper*, or cherry, whose thorns are eight inches in length, and serve as knitting needles; the wild orange, which supplies excellent wood of a fine yellow colour. The *floripondio*, remarkable for the beauty of its form, and the ambery fragrance of its flowers, which, by uniting its branches at the top, exhibits the appearance of a spherical crown; a single floripondio is sufficient to perfume a whole garden. The *canello* or Winter's bark, held sacred by the Araucanians, who carry branches of it on religious occasions, and, after concluding a peace, present them to the enemy as a token of reconciliation and friendship. The *carob tree*, remarkable for the extreme hardness of its thorns, which are sometimes employed instead of nails. The *maqui*, a species of cornel, from whose berries the Indians procure a sort of beverage called *theca*; in the juice of its leaves it affords a specific in cases of sore throat. The *luma*, or lofty myrtle, attains the height of 40 feet, and is exported to Peru for the use of coachmakers; the wine of its berries is reckoned a powerful stomachic. The *quillai* is a new genus, and named from the Chilian word *quilcan*, to wash; its bark, when reduced to powder, and sufficiently moistened, foams like soap, and supplies the domestic purposes of that substance. It is even more efficacious than soap in cleansing woollen cloths, but is apt to induce a yellowish tinge when applied to linens. The wood is so hard and tough as to be used in place of metal for stirrups. The *lithi*, or caustic laurel, gives out, in summer, an effluvia of a very peculiar quality, and operating only on certain constitutions. In some it occasions painful swellings or pustules, on the face and hands, either when stopping under its shade, or passing near it, while on others it has no sensible effect. Its leaves, which are oval and wrinkled, are of a dark green, and an inch in length; the fruit is similar to that of the common laurel; its wood is employed in houses and shipbuilding, and is valued for the extreme hardness which it acquires by remaining for some time under water. The *bollen* is found upon the sea coast, and, in point of appearance, is one of the finest trees in Chili; it is reckoned highly poisonous; the buds, however, when pulverized, are given by physicians as a powerful emetic, the dose not exceeding half a scruple; the *mayten* is a beautiful evergreen, of a new genus, found in the vicinity of the lithi; and affording an antidote to its poison; the *patagua*, whose trunk will sometimes measure eight yards in circumference, is much valued for a small flower in shape and smell resembling the lily. Chili, in its fruit trees, is greatly inferior to the tropical countries of America. The principal of them are the cocoa nut, the guevin, the pehuen, the peumo, and the lucuma. The fruit of the Chilian *cocoa nut* does not exceed in size a walnut; it grows in bunches containing sometimes a thousand individual nuts. The kernel is well tasted, and supplies an excellent oil. The *peheun*, or Araucanian pine, is by some supposed to be a new genus; its branches form a quadrangular pyramid; the leaves are three inches in length, heart-shaped, hard and shining; its fruit attains the size of a man's head, and in taste resembles the chesnut. The *peumo* is a new genus, having four species, and many varieties; the fruit of one of these (the *peumus mammosa*) yields kernels so hard as to serve for rosaries to the inhabitants; the bark is employed in tanning leather, and in dyeing. The fruit of the *lucuma*, which is also a new genus, in taste and size is somewhat similar to the peach. The various kinds of European fruit trees, vines, pulse, garden herbs, and flowers, are all found to succeed, and many of them to improve in Chili. Indeed, so favourable is its climate to vegetation, that at the same time, in the same orchard, fruit may be seen in all degrees of progress, in the bud, in the flower, green, and perfectly ripe. Pear and cherry trees produce twice a year. Extensive forests of apple trees are found in the province of Quillota, while oranges, lemons, and citrons, occur every where in the open fields. The grapes raised on the banks of the river Plata are most esteemed, and afford a sort of muscadel called Conception wine, which is equal to the best wines of Europe. The melons are excellent in their flavour, of an elongated form, with a very slender rhind. Among the numerous varieties, the musk melon and the *scritti* are the first in estimation.

Shrubs.

Among the shrubs, the most remarkable are the *thuraria*, of a new genus, and equal in its properties to that of Arabia; the *puga*, which supplies the inhabitants with cork, and which presents a very fantastical appearance, putting out from its root three or four trunks, in length about 20 inches, and as much in diameter; the *tuna*, a species of Indian fig, and equal to any of those in Europe; the *kali of Alicant*, in great abundance; and a certain climbing shrub which affords an alkaline salt for the use of soap boilers. Besides these are seven species of myrtle, of which the most valuable is the *agni*, or murtella, yielding a pleasant odoriferous liquor, which is reckoned superior to the best muscat. There are many shrubs likewise of a medicinal quality, which the native Chilese have understood and employed from time immemorial. Among these we may notice the *cullen* (*psoralea glandulosa*) indigenous to Chili, and well known as a powerful stomachic and vermifuge, the leaves of which, with those of the yellow cullen, a shrub of the same species, affords a balsam of amazing efficacy in the cure of wounds; a species of *acacia*, or mimosa, named *jarello*, which, from its branches, gives a vulnerary balsam. The root of the *guacuru* is also employed as a specific for all sorts of wounds, being of a quality powerfully astringent; it is used also with great success in cases of ulcer, scrophula, and dysentery. The expressed juice of the *palqui* is of excellent effect in inflammatory fevers; the wood is extremely brittle, and is employed by the Indians for producing fire. "This they accomplish," says Molina, "by friction, turning rapidly between their hands a small stick of this wood, in a hole made in another piece of the same kind."

Medicinal.

Herbs.

The herbage, particularly in the vallies of the Andes, is so tall and luxuriant, as entirely to conceal the sheep that pasture among it. There are three species of poisonous herbs which occasion madness in the animals that happen to browse them, especially in horses. The most injurious of these herbs is the *hippomanica*, which if a horse eat he will certainly die, unless immediately thrown into profuse perspiration. Of the alimentary herbs, the most valuable are the *gua*, or maize, which was the only species of corn cultivated in America before its discovery by Columbus, and still continues to be a very general crop in Chili; a species of bean called *degul*, and the *quinua*, a kind of chenopodium, which affords an agreeable stomachic beverage; the *magu*, a sort of rye, and the *tuca*, a species of barley, have been superseded in the estimation of the Araucanians, by the European wheat, which is now cultivated in their room. The potatoe is indigenous to America, and M. Bomare considers Chili as its native soil. There are two species of it, with about 30 varieties. The root of one of these (the *solanum cari*) is in shape cylindrical, and sweet to the taste. There are two species of the gourd, the white flowered gourd, and the yellow flowered; of the first are many varieties, some yielding a fruit that is sweet and nourishing, others a bitter fruit which is employed to ferment cider, and which, being of a large size and spherical, furnishes the inhabitants with their calabashes.

Alimentary.

The *quelghen*, or the strawberry of Chili, frequently attains the enormous size of a hen's egg, and differs farther from that of Europe in the roughness and succulency of its leaves; it is of three kinds, the red, the white, and the yellow; the two first are the most frequent; the yellow is found chiefly in the provinces of Puchacay and Huilquilemu. The seeds of the *madi*, a new genus, supply an oil which has been preferred to any of the French olive oils. Three species of the *pimento* are employed in seasoning. Besides these, and many other alimentary herbs, there is, in the province of St Jago, a particular species of wild *basil*, from whose leaves the inhabitants gather, every morning, a kind of salt, which in taste far exceeds the common salt.

Herbs used for dyeing.

Certain vegetable dyes have been long employed with success by the Chilians, producing lively and very durable colours, which yield neither in washing, nor by exposure to the air. The *relbun*, a species of madder, furnishes a beautiful red; yellow is obtained from a species of agrimony, and a kind of cress named *poquel*, the stalks of which supply also a green colour. The berries of the *cullen* give a violet; and the root of the *panke*, a perennial plant, yields a fine black, which, besides its use as a dye, possesses likewise the properties of an excellent ink.

Medicinal.

A knowledge of medicinal plants forms the whole medical science of the unconverted Chilians, who are careful to exclude all strangers from any participation in their accumulated experience. Without the advantages, however, of this desirable aid, there have been discovered nearly 200 medicinal herbs, the principal of which are the *cachanlahuen*, celebrated for its efficacy in fevers, sore throats, and pleurisy, and also as a purgative, dissolvent, and vermifuge; the *vira vira*, a kind of houseleek, extremely aromatic, and used in intermitting fevers, the infusion of which is sudorific, and given in catarrhal complaints; the *retamilla*, which possesses qualities similar to those of the vira vira; the *payco*, which is an excellent stomachic, and of much benefit in pleurisy; the *quinchamali*, whose juice is applied to bruises; the *pichoa*, the *clinclin*, and the *guilno*, all of them purgatives; the *diuca-lahuen*, vulnerary; and the *corecore*, a specific for the toothache. Chili affords two kinds of cultivated tobacco, the common, and the little tobacco, of which the last is by far the most powerful.

Climbing plants and grasses.

Of *climbing plants*, the most remarkable is the *cogul*, which having reached the top of one tree, immediately begins to descend, and in a short time has attained the summit of another, from which it proceeds in the same manner to a third; it has thus frequently been found to extend itself over a space of 200 yards. The stalk being tough, and extremely pliable, is used for baskets and cables, and these cables are said to be more durable even than those of hemp. The *pepoi* is used for similar purposes, in the Archipelago of Chiloe, and supplies excellent ropes for the Periaguas. We shall notice only two species of grass, the *quila*, whose stalk the Araucanians use for their lances; and the rush of Valdivia, which affords a handsome cane, is employed in the manufacture of cages, and serves the inhabitants as a covering for their houses.

Mallows, endive, trefoil, and some others, are common to Chili and Europe; lupins, love apples, celery, mustard, Spanish pimento, and cresses, occur in a wild state. Of tropical plants, are the pine-apple, the sugar cane, the banana, the cotton, jalap, mechoacan, and the sweet potatoe, all of which succeed in the northern provinces.

ANIMAL PRODUCTIONS.

Though Chili is not inferior to any part of the New World, in soil, climate, and vegetation, it must yield to the other countries of America in the number of its animal productions.

Quadrupeds.

The horse, the ass, horned cattle, sheep, goats, dogs, and cats, were early introduced by the Spaniards, and most of them, besides increasing in size, have greatly improved in their peculiar qualities. The *horses* are well shaped, swift, vigorous, and spirited. They are divided into three breeds, each named from its invariable and distinguishing gait. The *trotters* are the strongest, and much used by the country people; the *pacers*, remarkable for an easy, active, and well-supported motion, are principally used in long journies, in great demand, and preferred to the best horses of Andalusia; the *parade horses*, which never quit a foot pace, are only used on occasion of show and ceremony. These last are highly valued, and cost, about thirty years ago, from one hundred to five hundred crowns; while the price of a common horse did not exceed four shillings sterling. The mountain horses are harder and more robust than those of the plain, and their hoofs are so firm as only to require shoes when employed in cities. The peasants of Chili are almost perpetually on horseback, and not unfrequently perform journies of a hundred leagues upon the same animal, permitting him only to feed and rest during the night. The *ass*, more than any other European quadruped, has undergone a favourable and almost unaccountable alteration; but, though greatly surpassing the original stock in strength and size, is very seldom put to any use. It is found wild on the Andes, and hunted for the sake of its skin. The *mules* are strong, sure-footed, and active. The *horned cattle* have enjoyed a more than proportional share of the general improvement, and display different degrees of excellence, according to the richness of their pasture. The *oxen* of the midland provinces are of a larger size than those of the maritime, and are excelled, in their turn, by such as are reared in the vallies of the Andes; they are yoked to the plough in pairs, and drag it by means of a rope passed through their horns. It is a common practice among the land holders to fatten a thousand head of cattle, either cows or oxen, and to slaughter them at Christmas. Very little of this beef, however, is consumed in the country, but is chiefly disposed of in Peru. The *sheep* breed twice a year, and are equal to any in Spain. The breed has been crossed by the Pehuelches, and the result is an animal considerably larger than a sheep; its hair, which is often two feet in length, and somewhat curled, possesses all the softness of wool. The other quadrupeds we shall notice are indigenous to Chili. The *guemel* or *huemel*, in size, hair, and colour, bears a considerable resemblance to the ass, but differs from that animal in the formation of its ears, which are short and pointed; in shape also it is more handsome. The voice is a sort of neigh, and its teeth are exactly similar to those of a horse. It is fleet and headstrong, and found only in the most inaccessible regions of the Andes. The vicugna, chilihueque, and guanaco, in their manners and economy, are not unlike the camel; and, though greatly inferior in point of size, they somewhat resemble it also, in the structure of their internal parts: except the guanaco, however, neither of these animals have an arched back, and all of them, in the upper jaw, are completely destitute both of incisors and canine teeth. Their only defence, when attacked, or otherwise molested, is to squirt from their mouths a quantity of saliva, which is said to be of a caustic nature. The *vicugna* is about the size of a tame goat, but greatly exceeding it, in the length of its neck and legs. It inhabits the coldest and most precipitous ridges of the Andes, and has never been domesticated. Vicugnas are of a mild and timid disposition, and taken in great numbers for the sake of their wool. Being first compelled by the hunters into a narrow circuit, they are immediately surrounded by a rope, to which are attached, at short intervals, a great number of rags: and not daring to encounter this formidable barrier, they are, without difficulty, overpowered and put to death. The wool, which is of a pale rose colour and very fine, bears a high value in Europe. In the stomach is found the bezoar stone. The flesh, which affords an excellent nourishment, is sometimes applied externally in cases of ophthalmia. The *chilihueque*, or, as the name implies, the sheep of Chili, was originally called *hueque*, but the epithet *chili* was afterwards prefixed, in order to distinguish it from the Spanish sheep. It was anciently employed as a beast of burthen, and guided by a string passed through the rim of one of its ears. It has of late, however, entirely given place to the *mule*, which, for services of that nature, is now universally preferred. It is four feet high, and about six in length. The wool, which is long and soft, and not confined to any particular colour, is superior to the Spanish, and reserved entirely for the more costly articles. The *guanaco*, or *lua*, approaches the horse in size, and equals him in speed. It is hunted with dogs, but the old ones are seldom taken except by the Indians, who, being well mounted, and furnished with a *laqui*,[*] can strike and entangle them at the distance of three hundred paces. The guanaco is readily domesticated, and becomes often so extremely familiar as to follow its master like a dog. Its hair is employed in the manufacture of hats, and the flesh is prepared and put up for the use of seamen. Besides these, we may notice the *viscacha*, which, in its appearance, unites the fox and rabbit; the tail and colour being those of a fox, and the form of the other parts, as likewise its manners, connecting it with the rabbit; whose hair supplied the ancient Chilians with a very beautiful cloth, but is now manufactured into hats. The great *wood mouse*, which resembles the marmot in colour, while it doubles it in size, and is completely distinguished from that animal by its characteristic features; with several other kinds of mice, varying considerably in colour, habits, and dimensions. The *covur* or armadilla, of which there are four species. The largest of these is the *bola*, or eighteen banded, in length 13 inches; the *pichi*, or four banded, which is the least, measures only 6 inches. Of *carnivorous* animals, the most formidable is the *pagi*, or, as the Peruvians name it, the *puma*. Considered as a species, it seems to form a link between the lion and the tiger, though, in size and courage, it is greatly inferior to either. It is about five feet long, of a greyish ash colour dashed with yellow spots. Its head is round, like that of the cat, and like the cat also it is fawning and treacherous in its disposition. It is particularly destructive to horses, and upon discovering two of these animals fastened together in the fields, has been known to make sure of both, by first killing one, and while dragging it off, by striking the other with its paw and compelling it to follow and share the fate of its companion. Notwithstanding, however, its strength and dexterity, the *pagi* has learnt to dread the aspect of man, and a woman or child is often sufficient to scare it from its prey. It is hunted with dogs, and, while engaged in defence, a noose is secretly slipped over its head by one of the hunters. When thus entangled, it is said to "roar terribly and to shed a torrent of tears." The skin is manufactured into a strong leather, and afterwards converted into boots and shoes. There is a species of ferret called *chinghue*, which, when attacked, besprinkles its assailant with a sort of greenish oil, from a vesicle situated similarly with that of the polecat, of an odour so intolerably offensive as effectually to preclude any farther molestation. Assured of safety from this singular resource, it fears neither dogs nor men, and will boldly enter the houses in search of plunder, nothing daring to thwart its passage, or call forth its displeasure. There is but one method of destruction which the inhabitants venture to practise against the intruder. While some one engages its notice by caresses, another catches it up by the tail, and the muscles being from this position so much contracted, as to prevent the emission of its loathsome fluid, the animal is dispatched without apprehension. The odour reaches to a great distance, and repeated washings are necessary in order to purify garments that have once received its pollution. The skin is much valued by the Indians, who use it for bed-covers. There are likewise the *porcupine*, the *culpeu* or *wild dog*, *wild cats*, and *weasels*. In the rivers are found the *coypu*, a kind of water rat, equal in size to the otter, and capable of domestication; and the *guillino*, a species of beaver, in high estimation for the excellence of its fur. The sea contains a great number of *phocæ*, besides the *chinchimen*, which, with a strong external resemblance, possesses all the ferocious cruelty of a wild cat, and will dart upon any one that approaches it.

Birds.

A great number of birds occur in Chili which are common throughout Europe; such as kites, falcons, herons, gulls, swans, geese, ducks, plovers, crows, pigeons, partridges, and domestic fowls. Some of these are found in many varieties, but we shall notice only two: the *royal duck*, which is distinguished by its superior size, a large red comb which adorns its head, and a ring of white feathers about its neck; and the *red-headed heron*, whose plumage is of a pure white, except the beautiful crest, which affords its descriptive appellation. Partridges are said to be so extremely numerous, that the muleteers of St Jago, without almost needing to step aside from the road, knock them down in great numbers with their cudgels, and carry them for sale to Valparaiso. Of carnivorous birds, are the *jota* of the vulture tribe; the *tharu*, a kind of eagle, which instead of pursuing seizes its prey by stratagem; the *pequen*, a small owl, remarkable for the extensive burrows which it forms under ground, where it also deposits and hatches its eggs: But the principal of this tribe is the *condor*, in Chili called manque, which, from its enormous strength and rapacity, proves often extremely injurious in its depredations. Besides preying on sheep and goats, several of them will seize upon a calf, scoop out its eyes with their beaks, and instantly tear it in pieces. This bird is taken by a very simple contrivance. A peasant extended upon his back covers himself with the fresh hide of an ox, while others conceal themselves at a short distance; and when the condor, in expectation of a repast, alights upon the skin, its legs are immediately seized and held fast, till the assistants rushing forward, overpower it with their clubs. The

---

[*] "The *laqui* is a strip of leather, five or six feet long, to each end of which is fastened a stone about two pounds weight. The huntsman, who is on horseback, holds one of these stones in his hand, and whirls the other round like a sling, as swiftly as possible, in order to hurl it with more force, when he throws it at the animal he has singled out, which he is almost certain of striking."—MOLINA.

American *ostrich* differs from that of Africa, in having three toes in place of two, and in being entirely destitute of any horny substance upon its wings, and of callosities on the sternum. It is inferior also in size, but fully its equal in voracity, and will swallow iron if presented. *Parrots*, particularly the species named *jaguilma*, are remarkably numerous, and frequently lay waste the fields to a great extent: Fortunately they do not arrive from the Andes till after harvest, and in compensation, their flesh affords a delicious food to the inhabitants. Among birds of song, the *thenca* stands incomparably the first, both for the sweetness and variety of its music. In allusion to the last property, it has been called, in Mexico, the *centzontlatotle*, or the four hundred tongues. Its song gives the idea of a great number of birds uniting their voices in the most perfect harmony. The sprightly and active disposition of this bird cannot be reconciled to captivity, where it pines and dies. The *careu* is another of the thrush kind, which, besides its great powers of music and imitation, is remarkable for the singular propensity which it sometimes exhibits of destroying smaller birds, in order to feast upon their brains. There are three species of the humming bird, all of the most dazzling splendour, and some of them extremely diminutive: the smallest weighs only two grains. Among the aquatic birds, we may notice a species of *pelican*, whose sack, from its transparency, is employed for lanterns. The *flamingo*, which, from the length and formation of its legs, is unable, after the manner of other birds, to cover its eggs by stooping; but when hatching them has the ludicrous appearance of sitting upon a chair, the nest for its accommodation being raised in a conical form. The *pillu*, a kind of ibis, which is about the size of a goose, and remarkable for the length of its legs, which measure upwards of two feet and a half; and the *penguin*, of which there are several varieties.

Fish. Though it has been observed, in general, that the animal productions of Chili are less numerous than those of other countries in America, the remark does not hold in the case of fishes, which are found every where along the coast, and in the rivers in immense variety and profusion. Exclusive of the fresh water kinds, the fishermen are acquainted with 76 species of esculent fish, most of which are peculiar and entirely unknown in the northern ocean. Those most in request are the *robalo* and the *corvino*, both white in their flesh, and of a delicious flavour. The *lisa*, which in form and taste resembles the mullet, and the *king's fish*, so named from the excellence of its flavour. The *tollo* is remarkable for two spines of a triangular shape, very hard and crooked at the point; which are mentioned as a powerful remedy for the tooth-ach; the effect is simply produced by the application of one of these points to the diseased tooth. The following are common to other seas, the skate, the ray, the torpedo, the cod, the sole, the whiting, the turbot, the tunny and the mackerel; the barbet, the mullet, the anchovy, the electrical eel, and the sword-fish. At the islands of Juan Fernandez the cod is as plentiful and as readily taken as on the banks of Newfoundland. It has lately also been fished with success on the coast of Valparaiso, where it arrives in large shoals, during the months of November and December. The fresh waters of Chili supply fish in less variety, but in still greater numbers than the ocean. Of these, the finest are the *trout*, the *cauqui*, the *malche*, the *yuli*, the *cumarca*, the *lisa*, which is of the same species with the salt water fish of that name already noticed, but of a superior quality; and the *bagre*, whose flesh is yellow, and of all others the most esteemed as a [illegible]. Chili affords a great number of *crabs* and *crawfish*, remarkable for their size and goodness; *oysters*, *muscles*, *cocles*, *barnacles*, and several species of *molluscas*. There is also a kind of cuttle fish, individuals of which have been caught of a hundred and fifty pounds weight. Eels are confined to the provinces of Araucania, where they are taken in great abundance. In the river Talton is found a small fish called *paye*, which is represented by the natives as so extremely transparent, that any object placed under several of these animals piled the one above the other, would still remain perfectly visible. "If this property," says Molina, "is not greatly exaggerated, the paye might serve to discover the secret progress of digestion, and the motion of the fluids." *Whales*, equal in size to those of the northern ocean, make their appearance in great numbers in quest of fish, at the mouths of the Chilian rivers. Molina was himself witness to the dimensions of one of these animals, which had been cast ashore on the coast of the Chones, and which measured 96 feet in length.

Reptiles. Chili contains but few reptiles; these are the salt and fresh water turtles, lizards, frogs, toads, and a species of serpent, not exceeding three feet in length, which is perfectly harmless. Various incredible relations have been propagated of an immense water serpent, which is said to prey upon men and the larger animals, but have received little countenance from the more respectable authorities.

Insects. Of the insect tribe, we may notice a kind of *chrysomela*, which is of a bright golden colour, and when strung together like beads, is used by the inhabitants for necklaces and other ornaments; *caterpillars*, one of which, found between the rivers Rapel and Metaquito, produces a silk not inferior to that of Europe; a species of *water-fly*, which, from its agreeable musky odour, the inhabitants make use of to perfume their clothes. There are likewise bees, ants, scorpions, glow-worms, a single species of grashopper, and a few beetles. Chili is neither infested with gnats, wasps, nor musquitoes. Molina describes a *spider*, which he says is the only one known in the country, grows to the size of a hen's egg, and is quite inoffensive. Byron, however, mentions in his Narrative, a large venomous spider, whose bite will prove mortal, if proper remedies are not speedily applied. He was himself bit by one of them on the face, while at St Jago, and his whole cheek, in consequence, became perfectly black. The poison was extracted, he tells us, by the application of a bluish coloured stone, which sticks of itself to the wound, and drops off when saturated.

Manufactures. Though Chili supplies great abundance of raw materials, such as wool, skins, metals, flax, and hemp, the manufacturing industry has hitherto been extremely limited. The principal articles of manufactures are woollen stuffs, converted into cloaks, quilts, ponchos, carpets, stockings, and blankets; cordovan and sole leather, soap, skin-coats, saddles, and hats.

Commerce. External. The external commerce of Chili is carried on with Peru, Spain, and Buenos Ayres. About twenty years ago, twenty-three vessels were employed in the trade with Peru, each of 600 tons. They made three voyages annually, and exported wheat, wine, almonds, nuts, pears, apples, conserves, pulse, dried meat, neat-tongues, and cheese; besides, leather, tallow, cordage, copper, and timber for building. The imports, in return, were silver, iron, cloth, linen made at Quito, cotton, sugar, rice, cacao, sweet-meats, pickles, tobacco, oil, earthen ware, and all sorts of European commodities. The yearly exports amounted in value to 700,000 dollars. The imported articles were estimated at 500,000, leaving in favour of Chili a balance of 200,000 dollars. To

Buenos Ayres, Chili sends linen and woollen stuffs, partly imported from Peru, and partly of home manufacture; ponchos, sugar, snuff, wine, and brandy; and receives in exchange, wax, the herb paraguay, and negroes. The exports to Spain are gold, which amounted, at the abovementioned period, to 656,000 dollars; silver to the value of 244,000 dollars;[*] a few hides, and a small quantity of Vicugna wool; and in return, European goods were imported to the amount of a million of dollars: in both cases a considerable balance remained against Chili. The remittances of silver to Spain are conveyed, every summer, in two vessels, which also carry a part of the gold.

Internal.

The articles of home traffic are ponchos, carpets, stockings, blankets, skin coats, saddles, hats, and some others, intended principally for the use of the lower ranks, the higher class being in general supplied from the manufactures of Europe. Valparaiso receives provisions to the value of ten thousand dollars, and supplies the rest of the country with cedar. Chiloe sends to Valparaiso and Conception several kinds of valuable wood, woollen stuffs in the shape of ponchos, quilts, &c. besides dried pilchards and hams, in high estimation for their peculiar delicacy of flavour. The trade with the Araucanians consists in supplying them with edge-tools, toys, and wine; for which the Spaniards receive horses, horned cattle, and sometimes even children. The manner of conducting the exchange is thus described by Ulloa:

Traffic with the Indians.

"The Spaniard begins his negotiation by offering the chief of the family a cup of wine; after this he displays his wares, that the Indian may make choice of what best pleases him, mentioning at the same time the return he expects. If they agree, the Spaniard makes him a present of a little wine; and the Indian chief informs the community, that they are at liberty to trade with that Spaniard as his friend. Relying on this protection, the Spaniard goes from hut to hut, recommending himself, at first, by giving the head of every family a taste of his wine. After this they enter upon business, and the Indian having taken what he wanted, the trader goes away without receiving any equivalent at that time, and visits the other huts, as they lie dispersed all over the country, till he has disposed of his stock. He then returns to the cottage of the chief, calling on his customers in his way, and acquainting them that he is on his return home. Upon this summons, not one fails of bringing him to the chief's hut whatever had been agreed upon. Here they take their leave of him, with all the appearance of a sincere friendship; and the chief even orders some Indians to escort him to the frontiers, and assist him in driving the cattle he has received in exchange for his goods." A sort of fair is held annually on the Spanish frontiers by the Pehuenches, who, besides horses, cattle, skins, wool, gypsum, pitch, fossil salt, feathers, and ostrich eggs, expose also for barter many neat articles of their own manufacture, such as ponchos, bed covers, bridle reins finely wrought of plaited leather, baskets, wooden vessels, &c. for which they expect in return, wheat, wine, and some European commodities.

Government.

Civil and military.

The administration of the Spanish provinces is committed to an officer, residing one half of the year at St Jago, and the other at Conception, who is invested with the combined authority of president, governor, and captain general of Chili. During war, he is subordinate in some particulars to the viceroy of Peru, but is otherwise dependent only on the king. In his military capacity, he is at the head of the army, having under him the four governors of Chiloe, Valdivia, Valparaiso, and Juan Fernandez, the quarter-master, the sergeant major, and the commissary. In quality of president and governor, his jurisdiction is supreme in matters of a civil nature; he superintends and presides over the superior tribunals of St Jago, whose authority extends over the rest of the kingdom. Of these, the principal is the Royal Audience, celebrated for its justice and impartiality. It is divided into a civil and criminal court, the decisions of both of which are without appeal. Every province, besides a subdelegate who acts both in a civil and military capacity, has, or at least is directed to have, a municipal magistracy, called the Cabildo, established in the chief city of the province.

Military establishments.

The regular forces maintained in Chili by the king of Spain originally amounted to 2000 men, which number was afterwards reduced to 500, but has since that time been considerably augmented, to what particular extent we are not informed. There is, besides, a regular city and country militia. The number enrolled in 1792 amounted to 16,000 picked men, who were not required to perform the inferior duties of sentinels and patroles, but to exercise continually in arms, and to hold themselves in readiness for any sudden emergency.

Revenue.

The produce of the revenue offices was, in 1746, insufficient to defray the expences of the regular force, which did not then exceed 500 men. Since that period, however, the revenues have greatly increased: but we are not in possession of such data as might enable us to compute the amount.

Religious establishments.

The religion of Spanish Chili, like that of the mother country, is the Roman Catholic. Among the numerous orders of the Romish church, only five have succeeded in obtaining permanent establishments. The monks of the order of Mercy accompanied Valdivia from Peru. The Dominicans and strict Franciscans were shortly after introduced, under the same authority. The Augustines procured admission in 1595; and the Brothers of St John of God in 1615. The three first orders form separate jurisdictions. The Jesuits had established themselves in 1593, but upon the dissolution of the order, they were expelled from the territories of Spain. The Chilians are extremely averse to the admission of new fraternities, and have always resisted their establishment. The two bishoprics of St Jago and Conception comprehend, under their jurisdiction, the whole of Chili, besides the province of Cujo. To the diocese of St Jago belong Cujo, and all the provinces between Peru and the river Maule. The diocese of Conception comprehends, with the islands, the rest of Chili; the inhabitants, however, of this jurisdiction are chiefly pagans. At St Jago there is a commissioner of inquisition, with several inferior officers, delegated by the court of inquisition at Lima.

State of literature, fine arts, &c.

From the scarcity of scientific books and instruments, as well as the enormous expence of printing, literature and the fine arts were, about the year 1792, in a very low stage of improvement. Law is a favourite study, and many young men, after completing their academical course in Chili, proceed to Peru to be instructed in that science at the schools of Lima. The peasants compose a sort of rude verses, which though wanting in elegance and polish, are yet interesting from their extreme simplicity. They have also among them a sort of improvisatori, called *Palladores*, whose extemporaneous effusions obtain for them a high character, and form their only occupation. The mechanical arts, excepting those of carpentry and the working of metals, have made but little progress. A favourable impulse, however, has of late years been given to the arts and sciences in general, by a liberal patronage on the part of government, of which the good effects have already appeared.

---

[*] Humboldt estimates the value of the gold and silver furnished by the mines of Chili, from the period of the conquest up to the year 1803, at 29,571,021 pounds sterling.

Population. The population of Chili consists principally of Spaniards, Indians, and Mustees, besides whom are a few French, English, and Italians, and some Negroes. There exists no proper estimate of the general amount, nor any sufficient data by which to compute it; but it is certain, that the country is yet very far from being stocked with inhabitants. The encouragement given to commerce has proved particularly favourable to the Spanish population; that of the Indian provinces, however, has been considerably retarded by the immoderate use of spirituous liquors.

First inhabitants. The Spanish provinces were anciently possessed by the Copiapins, Coquimbanes, Quillotanes, Mapochinians, Promaucians, Cures, Cauques, and Pencons; most of which, once flourishing tribes, are now almost completely extinct, and the only remains of them are a few hamlets, the principal of which is *Laro* in the province of Maulé. These tribes, before the arrival of the Spaniards, had evidently attained some degree of civilization. They had established themselves in villages, each of which had an *Ulmen* or chief magistrate. They seem to have made considerable progress in agriculture: convenient and well-constructed aqueducts were employed in some districts to irrigate the fields; and there still remains a canal in the vicinity of St Jago, which, in its extent and workmanship, may be regarded as a standing monument of their industry and skill. They were acquainted also with the process of fermentation, and from their grain and berries obtained several kinds of liquors. In the manufacture of cloths, they used the spindle, the distaff, and two sorts of looms. They employed a variety of nets, the cord of which was procured from the plant *gnochia*. Hatchets of bell-metal-copper sometimes occur in the ancient sepulchres. They employed dyes, both vegetable and mineral, and of all colours; and fixed them by means of the stone called *polcura*. Their language was rich and harmonious, and contained terms to express the numbers ten, a hundred, and a thousand. But of all their attainments, the knowledge they displayed in astronomy and physic is by far the most remarkable. Of these, and of their religion, music, and military skill, a detailed account will be found in the article ARAUCANIA. To this article we must refer also for a description of their manners and customs; the Araucanians, as Molina observes, being still the faithful depositories of all the science and ancient customs of the Chilians.

Pehuenches. The tribes of native Chilians that still maintain their possessions and independence are the Araucanians comprehending the Puelches, to an account of whom we have just referred; the Pehuenches, Chiquillanes, Cunches, and Huilliches, allies of the Araucanians, but in some respects differing from that people in their manners and customs. The Pehuenches occupy that part of the southern Andes lying between the 34th and 37th degrees of latitude. They dwell in tents made of skins; and, for the convenience of pasturage, are continually changing their situation. They are expert riders, and spend the day on horseback: the bits which they use, as also the stirrups and spurs, are of wood. They frequently employ themselves in hunting the guanaco and ostrich, and use the *laqui* both in this exercise and in war. In dress they differ from the Araucanians, by covering the waist with a piece of loose cloth in place of drawers; and delighting in ornament, they paint their bodies, faces, and particularly their eye lids. Though possessing numerous herds of sheep and horned cattle, they live in general upon the flesh of horses. Of the other tribes, there is little mentioned deserving particular notice. Molina observes in general, of the mountaineers who inhabit the eastern vallies of the Andes, (including under that designation the Puelches, Pehuenches, Huilliches, and Chiquillanes,) that their complexions are much redder than those of their countrymen, who dwell to the westward of that mountain; "that they all dress themselves in skins, paint their faces, live in general by hunting, and lead a wandering and unsettled life;" that they are, "generally speaking, of a lofty stature and great strength, and no other than the celebrated Patagonians, who have occasionally extended their wanderings to the Straits of Magellan, and have at one time been described as giants, and at another as men little above the common stature."

The colour of the Indians, in general, is a copper brown; but the inhabitants of Boroa, a tribe in the heart of Araucania, are white, and in their features and complexion little inferior to the northern Europeans. M. Rollin, who accompanied La Perouse as surgeon major, describes the Indians whom he saw at Conception, as of lower stature than Europeans, their faces as larger and more rounded, the features more strongly marked, the eyes small, black, and deep seated, the forehead low, the eye-brows black and shaggy, the nose short and flatted, the cheek bones high, the lip thick, the mouth wide, and the chin diminutive. Very few of the native Chilians have almost any beard, being accustomed to pluck it out with pincers.

Language. They all speak the same language; a language remarkable for its regularity, softness, and power of expression. The Chilian is in no respect connected with the other American languages, and differs essentially from them all, both in its words and construction. The rules of its composition are simple and precise, and the theory of the language may be acquired with the greatest facility. There is not in its whole vocabulary one irregular verb or noun. It contains a great number of radical words; but the genius of the language consists in the formation of compounds, which are extremely numerous. Except the *x*, which is wanting, the Chilian alphabet is the same with that of the Latin. Like the Latin, also, its harmony is somewhat injured by a too frequent recurrence of the letter *u*. It does not, however, possess a single guttural letter or vocal aspirate.

Spanish inhabitants, manners, and customs. The population of Spanish Chili, as we have before noticed, has been considerably augmented since the removal of certain impolitic and oppressive restrictions upon maritime commerce. The wealthier inhabitants are in general fond of splendour and magnificence, which appears in their dress and equipage. The fashions are directed by those of Lima. Byron, who resided for some time in the country, gives the following description of the manners and customs of St Jago. "In their assemblies many intrigues are carried on, for they think of nothing else throughout the year. Their fandangoes are very agreeable. The women dance inimitably, most of them have delightful voices, and all play upon the guitar and harp: on the harp they excel every other nation. They are extremely polite; and when asked either to play, dance, or sing, they do it without a moment's hesitation, and that with an exceeding good grace. They have many figure dances; but what they take most delight in are more like our hornpipes than any thing I can compare them to, and upon these occasions they shew surprising agility. The women are remarkably handsome, and very extravagant in their dress. Their hair, which is as thick as can be conceived, they wear of a vast length, without any other ornament upon the head than a few flowers. They plait it behind in four plaits, and twist it round a bodkin, at each end of which is a diamond rose. In winter they have an upper waistcoat of cloth of gold or silver, and, in summer, of the finest linen covered with the finest Flanders lace. When they go abroad, they wear a veil, which is so contrived that one eye only is seen. Their feet are very small, and they value themselves as much upon it as the Chinese do.[*] Their breasts and shoulders are very naked, and indeed you may easily discover the whole shape from their manner of dress. They have fine sparkling eyes, ready wit, a great deal of good nature, and a strong disposition to gallantry. Paragua tea, which they call *matte*, is always drunk twice a day. They drink it through the conveyance of a long silver tube, at the end of which is a round strainer to prevent the herb getting through. And here it is reckoned a piece of politeness in the lady, to suck the tube two or three times first, and then give it to the stranger without wiping it. They eat every thing so highly seasoned with red pepper, that those who are not used to it, upon the first mouthful would imagine their throats on fire for an hour afterwards. The ladies sit cross-legged, after the Moorish fashion, upon the estrado, which is a platform raised about five or six inches above the floor, and covered with carpets and velvet cushions. The common vehicle is a calash or vis-a-vis, drawn by one mule only. Bull feasts are a common diversion here, and surpass any thing of that kind I ever saw at Lisbon or any where else."

Peasantry. The peasants are a healthy and robust race of men, chiefly consisting of Creoles. They are bold and dextrous horsemen, fond of riding, and almost ever on the saddle. They are amazingly expert, also, in the use of the *laqui*,[†] which is their principal weapon, employing it on all occasions, both in hunting and in their private quarrels. The Spanish Creoles possess all the estimable and engaging qualities which characterize those of English and French descent. They are brave, active, and enterprising, frank in their manners, and of the strictest honour. Their prejudices are few and easily eradicated. Their temper is generous and unsuspecting, but at the same time ardent and impetuous in the pursuit of pleasure, and too frequently transports them beyond the strict bounds of moderation. They are fond of learning, and possess a degree of penetration, sagacity, and correctness of thought, that might ensure success in almost any study.

The Spanish inhabitants, in general, are of a hospitable and generous disposition. As but few inns have been established in the country, their houses are at all times open to strangers and travellers, whom they entertain with a degree of kindness and liberality unequalled almost among any other people.

We may here notice a garment of very general use, both among Indians and Spaniards, which, though differing in quality and ornament, according to the rank of the wearer, retains always its peculiar and distinguishing form. It is called *poncho*, and consists of a piece of quilted cloth about three yards in length and two in breadth, having an opening in the middle just large enough to admit the head. It hangs down on all sides, serving completely the purposes of a cloak, while it leaves the motion of the arms more free and unembarrased.

Negroes. The negroes are wholly employed in domestic services, and treated with a degree of tenderness and humanity that greatly alleviates their state of servitude. They are protected from any extreme cruelty on the part of their masters, should these be so inclined, by a law permitting the slave, in a case of this nature, to demand, and obliging the master to grant, *a letter of sale*, by which the former is authorised to seek a purchaser. There exists also another regulation in their favour, which has the force of law among the inhabitants, that, when any one has, by his industry or good conduct, acquired a sum of money, sufficient to purchase a substitute, his master is bound to receive it, and set him at liberty. Negroes born in the country, and mulattos, are preferred to such as have been imported, as more readily attaching themselves to the families of their owners.

Diseases. No contagious disorder was ever experienced in Chili, till the arrival of the Spaniards, when the small-pox was first introduced, and raged, in some provinces, with the fatality of a pestilence. Since that period the Indians have contrived to save themselves from its ravages. When any one is suspected of having, from intercourse with the Spaniards, caught the infection, they immediately set fire to his hut by means of flaming arrows, and thus, by the violent sacrifice of an individual, arrest the progress of a distemper, which, if at first neglected, might eventually depopulate their provinces. Inoculation was introduced in 1761, by Matthias Verdugo, a monk of the order of St John. Chili is entirely exempted from many diseases peculiar to warm climates, such as the leprosy, the siam fever, and the black vomit. The rickets, hydrophobia, tertian and quartan agues, are unknown in the country. The most formidable disease to which the inhabitants are subject is a violent fever, sometimes prevalent among the peasantry, termed *chacao longo*, or the disorder of the head, from its being accompanied with delirium. The Indians cure it by certain herbs.

See Molina's *Natural and Civil History of Chili;* Byron's *Narrative;* Ulloa's *Voyages; English Universal History;* Perouse's *Voyage round the World;* Humboldt's *Political Account of New Spain;* and Kerr's *Voyages and Travels.* (U)

---

[*] La Perouse describes their shoes as so extremely short that the toes are bent double, which makes their feet appear almost round.

[†] This laqui differs from that used by the Indians, in having a single noose, in place of a ball at each end.—Ulloa informs us, that the Spanish peasantry can strike and halter the object of their attack, with almost unerring certainty, at the distance of 30 or 40 paces, but that a small distance, such as ten or fifteen paces, renders their dexterity in some measure ineffectual. He relates an instance of their address, with regard to an Englishman whom he knew at Conception. "This man was in the long-boat of a privateer, then lying in Conception Bay, intending to land at Talcaguana with a view of plundering the neighbouring villages, when a body of the country militia made to the shore in order to oppose them. Upon this the English fired upon them with their musketry; and no sooner had they discharged their pieces, than one of the peasants, though the boat was at a considerable distance, threw his noose, and, notwithstanding all in the boat threw themselves on their faces, he noosed the above-mentioned person, pulling him out of the boat with the greatest rapidity, while the others, instead of endeavouring to save him, thought of nothing in their fright but how to get out of danger as soon as possible."

CHILODIA, a new genus of plants of the class Didynamia, and order Gymnospermia. See BOTANY, p. 255; and Brown's *Prodr. Plant. Nov. Holl.* &c. p. 507.

CHILOE, or ANCUND, *the Archipelago of*, is situated in a large bay at the southern extremity of Chili. The original settlers, having emigrated from Chili, as is manifest from their manners and language, gave it the name of *Chil-hue*, (hence Chiloe), i. e. a district of Chili. It is bounded on the north and east by the continent, on the west by the Pacific Ocean, and on the south by the Archipelago of Guaytecas. As a province of Chili, it comprehends a small portion of the continent, extending to the district of Osorno on the north, and to the Cordilleras on the east. Its discovery, in 1558, by Don Garcia de Mendoza; the unresisted subjugation of its inhabitants in 1566, then amounting to 70,000, by a troop of sixty Spaniards under Ruiz Gamboa; and their feeble endeavour, at the commencement of the last century, to recover their independence;—these transactions are briefly noticed in the history of Chili, and we shall not here repeat them. The number of islands in the Archipelago, comprehending the Chones which are dependent upon it, does not exceed 82, of which 32 are inhabited. The island of Chiloe, or Isla Grand, is by much the largest in the Archipelago. It lies at the mouth of the bay, and extends in a direction north and south from the 41st and a half to the 44th degree of latitude, forming two straits or passages with the continent: the passage at the northern extremity is about a league in breadth; the other is upwards of twelve leagues. In this, as in the other islands, the land is considerably elevated, and rises into mountains, overspread with impenetrable thickets: It contains forty-one settlements. The other islands are of very insignificant dimensions, except a few that measure in length from twelve to fifteen leagues. Six settlements have been established on the Isle of Quinchau; Laicha and Lemui contain each of them four; Calbuco has three, and the rest only one each. These settlements cannot properly be denominated towns, as in most of them the houses lie dispersed, and at a considerable distance from each other.

Towns.

The only towns in the Archipelago, are the city of Castro, Chacao, San Carlos, and Calbuco. *Castro*, founded in 1566, by Ruiz Gamboa, is the capital of the province, and stands on an arm of the sea, in south latitude 42° 58′, west longitude 303° 15′. *Chacao*, acknowledging the same founder, was, previous to the erection of San Carlos, the principal sea-port, and the residence of the governor: it is situated in 42° of south latitude, and 307° 37′ west longitude. The harbour affords good anchorage, though somewhat exposed to the north and north-east winds; but the entrance, from the rapidity of the currents, and certain hidden rocks in the middle channel, is rendered extremely hazardous. *San Carlos* is now the principal port, and the seat of government; and though founded so late as the year 1768, is superior to all the other towns, both in prosperity and extent. In 1791, it contained 200 houses, occupied by more than 1100 inhabitants. It lies in south latitude 41° 57′. Though the harbour itself is good, frequent wrecks are occasioned at its entrance, by the sudden and overwhelming hurricanes which afflict these islands. *Calbuco* belongs to the island of that name, which is the station of a commandant, and lies at the north end of the bay.

Climate.

The climate of the Archipelago is temperate, and seldom incommoded by the extremes of heat or cold. It is sufficiently marked, however, by its excessive humidity: the rain falls in torrents, and continues often, without any intermission, to deluge the islands for the space of a month. Except in the autumnal season, eight days of fair weather is a very rare and unexpected occurrence. During that season, however, the Chilotes commonly enjoy a respite of several weeks. These rains are seldom accompanied by thunder or lightning, but they are attended with frequent hurricanes, which sometimes prove extremely injurious. Owing to the rocky and mountainous character of these islands, cultivation is almost wholly confined to the plain grounds near the coast; the interior contains a few cultivated vallies. The degree of tillage given to this small portion, if we may judge from the extreme rudeness of the agricultural implements, must be very imperfect. Two crooked stakes, sharpened at the point, are made to serve the purpose of a plough, and both are worked by a single labourer. He seizes a stake in each hand, and applying the heads to his breast, forces their points into the ground, and turns up the soil by extreme exertion: the labour is considerably augmented by the vast number of myrtle roots which every where abound throughout the cultivated lands. The seed, previous to this scratching, has been scattered over the ground, which has also received a sufficient quantity of manure from the flocks of sheep which, for that purpose, are always made to pasture upon it, for three months before cultivation.

Cultivation and vegetables.

The excessive moisture of the climate, though no way injurious to its salubrity, is extremely unfavourable to the interests of agriculture. On account of the weather, it is always necessary, in order to save the crop, to cut it down before it is perfectly ripe, often when it is yet green, and to dry it in sheds and barns. Wheat, notwithstanding these disadvantages, gives a tolerable crop, yielding, at an average, twelve for one. Maize and barley succeed well; several kinds of pulse are cultivted with success; but the principal crop is potatoes, which are large, and of the very best quality. Bread is considered as a luxury, especially wheat bread, and is confined almost exclusively to the houses of the more wealthy inhabitants. An excellent substitute is afforded by the *luche*, a marine plant, which being sufficiently dried, is afterwards, by some unexplained method of preparation, converted into loaves. From their barley, reduced to meal, the Chilotes obtain a pleasant sort of ale, called *chica*, which will intoxicate if taken in considerable quantity. Of fruits, the number is very small, and none of them reach maturity except apples and strawberries, which grow wild, and in great abundance. The woods supply the *alerce*, or red cedar, a large and beautiful tree, of which a single stem will afford from six to eight hundred boards, each twenty feet long. Its wood is of a very singular quality, and, from its peculiar evenness of grain, can be divided as exactly, with the assistance of a few wedges, and formed into boards as smooth and level as if the finest saw had been used in the operation. The bark is employed as oakum, and serves the purpose well for those parts of a ship that remain under water, but it will not stand exposure to the sun or atmosphere. We may notice also the hazle, the cypress, the *luma*, a species of myrtle, and the ciruelillo, all of them used as articles of commerce.

Animals.

Of domestic animals, the most numerous are sheep and hogs. The wool of the sheep gives employment to the female Indians, who manufacture it into ponches. The hams of Chiloe are reckoned the finest in South America. All attempts to introduce the ass have proved ineffectual; those transported having constantly perished a short time after their introduction. The horse and the ox have succeeded better, and their number is now considerable. The principal wild animals are otters, deers, and foxes, of which the last are black, equal in size to the European fox, and corresponding with the blue fox of Chili. Fowls also are numerous, both wild and domestic. One of the most useful is the *quethu*, a species of penguin about the size of a common duck: its body is furnished with a soft ash-coloured plumage, the texture of which approaches so near to wool or fine hair, that it is spun by the natives, and woven into beautiful bed covers. It is about the size of a domestic goose, never appears in flocks, but remains always in pairs. The sea, as if to compensate for the natural deficiences of soil and climate, supplies, in the most profuse abundance, almost every sort of fish. A very summary method is employed to obtain them. A large extent, at the mouths of rivers and other favourable situations, is enclosed with palisades, the vacuities between which are occupied with a sort of basket work; an opening is left towards the sea, and this is carefully secured before the tide begins to ebb. By this simple contrivance, such quantities of fish are sometimes taken, that numbers will remain untouched in the enclosure, after all the inhabitants in the neighbourhood, and others from a considerable distance, have supplied their wants. *Whales* of a great size have been cast ashore on the opposite continent. Among the numerous *Phocæ* that inhabit these seas, the *lume*, or sea elephant, which occurs in the Archipelago, is by much the largest. Individuals have been taken of this species measuring in length 22 feet, and 15 feet in circumference.

Manufactures and commerce.

The Chilotes possess few materials for manufacture; their principal articles are ponchos, bed coverings, blankets, rugs, carpets, embroidered girdles, and linen cloth. Much industry and neatness of workmanship are employed in weaving a poncho: this manufacture is performed by the women, without the assistance of a loom, the warp being extended and made fast by means of pegs: the operation, however, is altogether so tedious, that two ponchos are commonly the whole production of a woman's labour during a year. Besides, the above article of manufacture, the Chilotes export hams, pilchards, dried shellfish, and ambergris; white cedar boxes, cedar boards, the wood of the luma for poles of coaches and axle-trees, and hazle for ship-building; these they barter for sugar, wine, brandy, tobacco, salt, herb of Paraguay, and some European commodities. This small commerce was carried on in 1792 by four vessels from Chili and Peru, which paid an annual visit to the Archipelago. When any of these vessels arrive at San Carlos, the natives assemble from all quarters to dispose of their surplus goods; and, in order to prevent imposition, the exchange is regulated by the Cabildo or municipality of the town, who set a value upon the articles for barter.

Government, religion, &c.

The affairs of the province are placed under the administration of a Spanish governor, who resides at San Carlos, and is immediately dependent on the captain-general of Chili. A commandant is stationed in the island of Calbuco; and in the city of Castro, there is a magistrate or cabildo, whose office it is to determine the private suits of the Indians. The Indians are divided into seventy-six ulmenates, some of which are subject to the Ulmens of the district; but most of them are under the immediate cognizance of Spanish officers. Though the feudal practice of requiring personal service be no longer enforced in the other provinces of Chili, fifty days service is still rigidly exacted throughout the Archipelago. San Carlos is furnished with a garrison of fifty-three dragoons, fifty-three infantry, and thirty-three artillerymen. The militia of the province amounts in all to 1569 men, who must perform garrison duty without pay. In its religious concerns, the Archipelago belongs to the diocese of Conception, and contains three parishes. There are two convents, one of Franciscans, the other of Mercedarii, which are the residence of a few monks. The Jesuits had a parish church and a college.

Population.

The population consists of two distinct classes, Spaniards and Indians. It is a curious fact, that these separate races have at no time intermingled, as in the other provinces. According to the latest accounts from the Archipelago, the total amount of the inhabitants was computed at 26,000, of which 15,000 were Spaniards. At the period of their submission to the Spaniards (1566), the Indian inhabitants amounted to 70,000. In the year 1792, they did not exceed 11,000. Are we to ascribe this otherwise unaccountable reduction to the murderous tyranny of the Spaniards? The submissive Chilotes afforded little pretence for open violence; and if violent means were not employed, how cruelly laborious and oppressive must be that servitude, which could so exhaust a flourishing population. In their appearance, dress, and cutsoms, the Chilotes differ little from the continental Chilians. Their language was originally the same as the Araucanian or Moluche, but of late years a remarkable change has taken place in this respect: they have gradually adopted the Spanish vocables in room of the Chilese; while of the latter, they have minutely retained not only the syntax and idioms, but even the inflections and accent. Byron describes these people as of a robust but not inelegant make, extremely well featured, and remarkably neat in their dress. The poncho is in general use among them. They wear a sort of buskin on their legs, which, however, does not not extend to the feet; these always remaining uncovered, as in such a climate shoes would only serve to retain the moisture, without the possibility of preventing its admission. The Chilotes possess a remarkable quickness of apprehension, and learn readily whatever is made the object of their study. They display a strong mechanical genius, and have attained considerable excellence in carpentry, cabinet-making, and turnery. The disposition most prevalent among them is that of gentleness and timidity; yet the Chilotes yield to no other people in the firmness with which they encounter the perils of a tempestuous ocean. They are fearless and active sailors; and it deserves remark, that a people possessed apparently of so much physical and moral energy, accustomed daily to brave the most imminent hazards, and to endure the severest fatigues, should, with such inglorious facility, have submitted their lives, their possessions, and their freedom, to the tyrannical disposal of a few strangers. The Chilotes readily embraced the doctrines of Christianity, and they continue to observe its duties with an exemplary strictness. The Spaniards born in the Archipelago are in general of a robust and healthy constitution. The Spanish women are well-complexioned, and tolerably handsome, but they disfigure their faces, in a ludicrous manner, by their mode of painting.

The houses in the Archipelago, whether of Spaniards or Indians, are mere hovels. They are entirely built of wood, and consist commonly of a single apartment, in the centre of which is placed the fire; and as there is no regular chimney, the roof is furnished with two small openings, one at each end, which serve as vent holes for the smoke (U)

CHIMARRHIS, a genus of plants of the class Pentandria, and order Monogynia. See BOTANY, p. 146.

CHINA.

Topography.
Extent.

CHINA PROPER, an immense country in Asia, extends about 18 degrees from north to south, and nearly an equal distance from east to west. It is bounded on the east by the sea; on the west by lofty mountains and extensive desarts; on the south by the ocean, and the kingdoms of Tunkin, Laos, and Cochinchina; and on the north by the regions of Tartary, from which it is divided by a stupendous wall 1500 miles in length.

Name.

By the Chinese, their country is called *Tchong-Koué*, or the middle kingdom, because they formerly imagined, that it was situated in the centre of the earth, and that all other countries lay scattered around their empire in the form of small islands. In later times they have, indeed, acquired a more correct geography; but so inveterately do they adhere to ancient opinions, and especially to whatever flatters their national vanity, that they still continue to express themselves in this erroneous manner, and to preserve unaltered every sentiment and expression of their great philosopher Confucius. By the western Tartars, it is called *Catay*; by the Mantchew Tartars, *Nicancourou;* by the Japanese, *Thau;* and by the natives of Siam and Cochinchina, *Cin*. It is supposed, that the word China is derived either from this last appellation, or from *Tsin*, or *Tai-tsin*, the name of the first imperial family, who carried their arms towards the west.

Division.

China is divided into fifteen provinces; Pe-tchelee, Shansee and Shensee, situated towards the north and north west; Setchuen and Yunnan, on the west; Quansée and Quanton, on the south; Fokien, Tchekian, Kiannan, and Shantong, on the east; and Honan, Houquang, Koetchou, and Kiangsée, in the middle region. Of these provinces a very laborious and accurate survey was made by order of the Chinese government, under the direction of the Jesuit missionaries, in which they are said to have employed a period of ten years, and of which a beautiful manuscript map, by a Chinese, is deposited in his majesty's library at Buckingham house.

Pe-tchelee.

I. PE-TCHELEE, *Tchelee*, or *Li-pa-foo*, is the principal province of the empire; and its capital, Pekin, is the ordinary residence of the court. This city is situated in a fruitful plain, about 20 leagues distant from the great wall of Tartary. Its name signifies *the northern court*, which distinguishes it from Nankin, *the southern court*, where the emperor formerly resided; but found it necessary to remove nearer to the northern boundaries of the empire, to repel more effectually the frequent incursions of his Tartar neighbours in that quarter.

Pekin.

The city of Pekin forms an oblong square, inclosing an area of 12 miles, exclusive of the suburbs, and is divided into two towns, the one inhabited by Tartars, and the other by Chinese. This division, or rather addition, took place at the Tartar conquest, when the new sovereign crowded the capital with such numbers of his own nation, that the Chinese were under the necessity of building a new city without the walls of the old one. The walls of Pekin, especially of the Tartar city, are of considerable height and breadth, and are formed of two lines of brick or stone, the middle space being filled up by the earth, which is dug out of the surrounding ditch. They are generally 30 feet high, 25 feet thick at the base, and 12 feet across the top within the parapets. There are nine lofty and arched gates, (whence Pekin is sometimes called "the city with nine gates,") of which three are placed in the south wall, and two in each of the other sides. Over each gate is a large pavilion-roofed tower, divided into nine stories, with port-holes, or apertures, in the wall; and, before each of the gates, is a large open space, inclosed by a semicircular wall, equal in height and thickness to that which surrounds the city. At each angle of the city wall, also, is a similar large square building, rising above the parapet to the height of four stories; and, in each of the sides, there are, on each floor, fourteen windows or port-holes. These structures are now used only as public granaries, or rice magazines. Along the whole course of the wall, at the distance of a bow-shot, or 70 yards from each other, are spacious towers, projecting about 40 feet from the line of the wall, with a small guard-house on the summit of each.

Topography

Emperor's palace.

The middle gate of the south side opens into the emperor's palace, which is situated in the centre of the Tartar city. This imperial residence comprehends a vast assemblage of immense buildings, extensive courts, and magnificent gardens. It occupies a space about a mile in length, and three quarters of a mile in breadth, and is inclosed on all sides by double walls of red polished bricks, 20 feet high. Through the middle of this inclosure winds a considerable rivulet, formed into canals, basons, and lakes, and adorned with artificial rocks, mounts, and grottos. This palace is peculiarly distinguished by the singular structure of its pavilion roofs, which are covered with varnished tiles of so brilliant a yellow, as to have the appearance, at a distance, of being gilded.

Between the other two gates on the south side, and the corresponding opposite gates in the north wall, run two parallel and straight streets, each about four English miles in length, and 120 feet in breadth. Of the two streets which stretch, in like manner, from the two eastern to the opposite western gates, one is equally wide and straight as the other main streets; but the other is interrupted by the north wall of the palace, round which therefore it is carried in its progress. The cross streets are only lanes branching from these principal streets in right angles, exceedingly narrow, but filled with houses of the same appearance as the larger streets. The main streets are lined on every side with shops and warehouses, before which the goods are brought out and displayed in various groups. In front of these shops, are generally erected large wooden pillars, higher than the eves of the houses, with inscriptions upon them in gilt letters, describing the nature of the wares within, and the reputation of the dealer; and, in order to attract the notice of passengers, they are hung with various coloured flags and ribbands from top to bottom, so as to have the appearance of a line of shipping dressed. The sides of the houses also are painted with different colours, chiefly sky-blue or green, mixed with gold. The streets are not paved, but covered with sand and dust, on account of which the cross lanes are frequently watered.

At the points, where the great streets intersect each other, are erected monuments or triumphal arches, in memory of those, who have attained remarkable longevity, or distinguished themselves in the service of the state. These structures consist of a large central gateway, with a smaller one on each side, covered with narrow roofs;

Topography. are built sometimes of wood, but generally of brick; and are varnished and painted, like the houses, in a very splendid style. There are abundance of wells throughout the city; but, the water is extremely bad. Within the northern wall, also, is a large sheet of water, several acres in extent, and a small stream running along the western wall, which supply the neighbouring districts. There are no common sewers to carry off the dirt and dregs of the city; but, from the scarcity and value of manure in China, no kind of filth or offensive substance is ever thrown out into the streets. Every family collects its own refuse into a large earthen jar, the contents of which are sold for money, or exchanged for vegetables from the gardeners. In consequence, however, of the preservation of these various kinds of excrement in the houses, and the multitude of little carts employed in conveying it to the neighbouring fields, the air of the city is filled throughout with a very disgusting odour.

Population. No correct idea can be formed of the population of Pekin, or of any Chinese city, from the extent of the inclosing walls; as they have, in general, within their compass large patches of unoccupied land, which often exceed the space of ground upon which the buildings stand. In that part of the capital called the Chinese city, several hundred acres are in cultivation; in the imperial residence, more than two-thirds of the whole are occupied by parks or pleasure grounds; and under the north wall of the Tartar town, as has been already mentioned, is a large pond or swamp about 50 acres in extent. These spaces of open ground are supposed to have been reserved, as appears also to have been done in several of the celebrated ancient cities of Asia, for the purpose of yielding a supply of onions, garlic, and other pungent vegetables, during the time of a siege.

Appearance. The external appearance of Pekin does not excite very high expectations in the mind of the traveller; as none of the buildings can be seen over-topping the wall, and not even a chimney rises above the roofs of the houses. Neither has the inside view much variety of aspect, as every street is laid out in the same manner, and every house built upon the same plan. The streets and lanes are disposed in straight lines, and the houses all of the same height, seldom exceeding one story; and, except the great shops, none of them have any windows towards the street in front; so that the whole has more the appearance of a large encampment, than of an ancient city. But the bustle and number of its moving objects, present a sufficient variety and succession of scenery to the view. The cross streets or lanes are said to be extremely quiet, and free of crowds; but the great streets, which lie in the direction of the gates, and which are the only outlets to the city, are constantly thronged with people. The following striking description by an intelligent eye-witness, will give the best idea of the busy scene. "The multitude of moveable workshops of tinkers and barbers, coblers and blacksmiths; the tents and booths, where tea and fruit, rice and other vegetables were exposed for sale, with the wares and merchandise arrayed before the doors, had contracted this spacious street to a narrow road in the middle, just wide enough for two of our little vehicles to pass each other. The cavalcade of officers and soldiers, that preceded the embassy; the processions of men in office attended by their numerous retinues, bearing umbrellas and flags, painted lanterns and a variety of large insignia of their rank and station; different trains, that were accompanying, with lamentable cries, corpses to their graves, and, with squalling music, brides to their husbands; the troops of dromedaries laden with coals from Tartary; the wheel-barrows, and hand carts, stuffed with vegetables, occupied nearly the whole of this middle space in one continued line, leaving very little room for the cavalcade of the embassy to pass. All was in motion. The sides of the streets were filled with an immense concourse of people, buying and selling and bartering their different commodities. The buz and confused noises of this mixed multitude, proceeding from the loud bawling of those, who were crying their wares, the wrangling of others, and every now and then a strange twanging noise, like the jarring of a cracked Jew's-harp, (the barber's signal made by his tweezers,) the mirth and laughter, which prevailed in every groupe, could scarcely be exceeded by the brokers in the Bank Rotunda, or by the Jews and old women in Rosemary-lane. Pedlars with their packs, and jugglers, and conjurers, and fortune-tellers, mountebanks and quack-doctors, comedians and musicians, left no space unoccupied." "The show of the embassy," adds the author, "was but an accessary. Every one pursued his business at the same time that he gratified his curiosity." [*]

The cities of China are divided into three classes, *Foo*, *Tcheoo*, and *Hien*; each of which comprehends a certain number of square leagues under its jurisdiction. Besides Pekin, the capital of the whole empire, the province of Pe-tche-lee contains 9 cities of the first class, 40 of the second, and 108 of the third. Those of the first order are Pao-ting-foo, which is the most considerable city in the province next to Pekin, and where the viceroy has his residence. It is situated in a pleasant and fruitful district; and is remarkable chiefly for a large lake in the middle of it, which abounds with the celebrated Chinese water lily, *lien-wha*. Hokien-foo, situated between two rivers, and noted for the cleanliness of its streets. Tching-ting-foo, situated on the banks of a beautiful river, is a well walled town, about four miles in circumference, and is celebrated for the medicinal plants, which are found upon the mountains in its neighbourhood. Shun-te-foo, is placed in the midst of a fertile and populous country, full of lakes and rivers, which abound in excellent craw fish; and its territory produces the best touch-stone in China, and also a fine kind of sand, which is used for polishing precious stones, and which is sold in every part of the empire. Quan-ping-foo, in the south of the province, is surrounded by a well-watered country. Tai-ming-foo, of which nothing worth mentioning is recorded. Yung-ping-foo, situated near the sea and encompassed by rivers, yields from its surrounding mountains abundance of tin. Suen-wha-foo, an extensive, populous, and well built city, situated near the great wall, and surrounded by fortresses. Its mountainous district yields very fine crystals and marbles, and a species of large yellow rat, the skins of which are much valued by the Chinese.

The province of Pe-tche-lee, extends from 38° to 40½° north latitude, and enjoys a fine clear atmosphere throughout the year. The temperature is various, generally about 80°, and occasionally 90° of Fahrenheit's thermometer during the day; but in the middle of winter, it frequently descends to the freezing point, and sometimes even to zero. According to the observations of Mr Barrow, the range of the thermometer in the month of August was found to be from 80° to 88° in the middle of the day, and during the night, generally, from 60° to 64°. In September, the medium temperature was about 76°. In October, about 68°, and at night as low as 44°. Its winter season is described as remarkably cold in proportion to its latitude; and the rivers are said to be so much frozen during four months of the year, that horses and waggons can pass upon the ice. The ice dissolves very slowly; the air, at the same time, is not so pinching to the feelings during these severe frosts as in Europe; and provisions of every kind may be kept for a long time without being subject to putrefaction. These circumstances have been ascribed to the quantity of nitre in the province, and to the serenity of the sky, which, even in winter, is seldom obscured by a cloud. There are very few mountains in the province; and the general face of the country is extremely level. At high water, it is not much more than two feet above the surface of the rivers; and the tide, which rises only nine or ten feet in the gulf of Pe-tche-lee, flows 110 miles into the bosom of the country, up the river Pei-ho, which frequently submerges the whole district through which it passes. Along the banks of this river a light sandy soil chiefly prevails, with a mixture of argillaceous earth, and slimy matter, interspersed with shining particles of mica; but not a stone of any magnitude, nor pebble, nor even gravel, is to be seen in the whole course of the river, as far as it is navigable. On the southern coast of the gulf of Pe-tche-lee, there are several hills all of the same size, and form regular cones with smooth sides, entirely detached from one another, and each standing upon its own base, so as to have all the appearance of having been artificially formed. The water in this province, especially near Pekin, when taken from the springs or rivers, leaves a kind of tartar of a yellowish colour in the vessels, in which it has been boiled, or has stood for some time. The plague never makes its appearance in this province, and the people are remarkably free from epidemic distempers. It has been remarked, that the inhabitants of this part of the empire have not the same aptitude in acquiring the sciences, as those of the more southern provinces; but they are much more warlike, hardy, and robust.

[*] Barrow's *Travels in China.*

Shan see.

II. SHAN-SEE, *Shang see*, *Chan-see*, or *Xan-see*, is one of the smallest provinces of the empire, but is considered as the spot where the first inhabitants of China, or at least the first founders of the nation, had their residence. It contains five cities of the first class, 16 of the second, and 70 of the third. Tai-yuen-foo, the capital of the province, is an ancient city, about three leagues in circumference, formerly the residence of the imperial family, but now much decayed in its splendour. The palaces of its royal inhabitants are reduced to ruins; and their tombs, on a neighbouring mountain, are the only memorials of their existence. These monuments are all of marble or cut stone, spread over a considerable space; mingled with triumphal arches, statues of heroes, figures of horses, lions, and other animals; and the whole surrounded by groves of cypress trees, planted in chequer. The territory around this city is fruitful and pleasant; and its principal articles of trade are hardware, stuffs of different kinds, but particularly carpets in imitation of those of Turkey. Pin-hiang-foo, nearly equal to the capital in the fertility of its soil, and the extent of its district. Lou-ngan-foo, pleasantly situated at the source of a river. Fuen-tcheoo-foo, an ancient and commercial city on the banks of the river Fuen-ho, famed for its hot-baths and springs, which attract numbers of strangers, and add greatly to its opulence. Tai-tong-foo, built near to the great wall, and well garrisoned, is a place of great strength, and has an extensive jurisdiction. Its vicinity abounds in medicinal herbs, lapis lazuli, marble, porphyry, and a beautiful kind of jasper. The climate of this province is pleasant and healthful; and the atmosphere generally pure throughout the year. The thermometer of Fahrenheit is often, for many days in winter, below the freezing point, and sometimes descends to zero. The soil is very fertile, and the vines produce the best grapes in China. It is full of mountains; some of which are entirely uninhabited, and have a very frightful appearance. But the greater part of them are carefully cultivated, and cut into terraces from top to bottom. On the summits of some of them are found extensive plains, which are said to be as fruitful as the richest low lands. They abound in jasper, lapis lazuli, marble, porphyry, iron ore, crystal, salt pits, and inexhaustible coal mines. The inhabitants are strong-limbed; and the women accounted handsome.

Shensee.

III. SHEN-SEE, *Chen-see*, or *Xen-see*, is divided into two parts, Eastern and Western, and is one of the most extensive provinces of the empire. It contains 8 cities of the first class, 22 of the second, and 84 of the third; of which the capital, Sin-gan-foo, is said to be inferior only to Pekin in beauty and extent. Its walls are strong and lofty, four miles in circumference, flanked with numerous towers, and surrounded by a deep ditch. It contains a palace, in which the sovereigns of China once resided; but the rest of its buildings are not much superior to those of other cities in the country. The principal Tartar troops, destined for the defence of the northern parts of the empire, are stationed in this city, in a separate quarter, inclosed by a wall of its own. In the neighbourhood of the city, is found a singular species of bats, as large, it is said, as domestic fowls, and the flesh of which is preferred by the Chinese to that of chicken. It was near this city, that the famous marble table, mentioned by Father Le Compte, was dug up, in the year 1645, which was considered as a monument of the Christian religion, and which was understood as demonstrating the existence of Christianity in China, as early as the period between 636 to 782. Han-tchong-foo, a large and populous city on the river Han, and remarkable for the high road in its vicinity, which is carried over very lofty mountains and deep vallies. Ping-leang-foo, a considerable city in the western part of the province, on the river Kin-ho, is surrounded with picturesque mountains, and numerous streams of water. In its vicinity is a valley so deep as to be almost impervious to the rays of the sun, and through the middle of which passes a high-way, paved with large square stones. Kong-tchan-foo, surrounded by inaccessible mountains, on one of which is to be seen an old sepulchral monument, which the Chinese consider as the tomb of Fo-hee or Fo-shee.* Lan-tcheoo, though only of the second order of cities, is one of the most important in the province, is the capital of the western portion, and the seat of the viceroy. It is situated near the great wall, and not very distant from the principal ports of the western coast. Its territories are watered by the great Yellow-river; and its trade consists in skins brought from Tartary, different kinds of woollen manufacture, and a coarse stuff made of cow's hair, used for great-coats as a protection from snow.

This province is celebrated for its wealth and commerce. Its soil is in general extremely fertile, and produces abundance of wheat and millet, but little rice. It is subject to excessive droughts, and destructive visits from locusts. It abounds in drugs, cinnabar, wax, honey, and inexhaustible veins of coal. It contains also gold mines, which the government does not permit to be opened; but gold-dust is washed down by the rivers in so great abundance, that numbers of the inhabitants gain their subsistence by collecting it. One of the most remarkable objects in the province, is the high-way cut across the mountains, and leading towards the capital; a work which was done at immense labour by the military during an expedition, and in the course of which are to be seen lofty bridges thrown over vallies, so high that it is fearful to look down, but at the same time so wide that four horsemen can ride along, abreast. The inhabitants of this province are said to excel the other Chinese in stature and strength, and likewise in genius and affability to strangers.

---

* The *h* in the Chinese language has always a sibilant sound before the vowel sound of *i*, *ee*, or *y*.

Se tchuen.

IV. Se-tchuen, *Se-thuen*, or *Sou-chou*, contains ten cities of the first class, 16 of the second, and 72 of the third, besides a number of forts and strong-holds. Tchingtoo-foo, its capital, was formerly an imperial residence, and one of the finest cities of China; but it was almost entirely destroyed in 1646, during the civil wars which preceded the last Tartar invasion. It still contains many magnificent ruins of palaces, bridges, and temples; and as it is situated in a plain, surrounded by canals and navigable rivers, it carries on a very considerable trade. Tchong-king-foo is one of the most trading towns in the province, in consequence of its favourable situation at the confluence of two large rivers, the Hin-tcha-kiang and the Ta-kiang. It is built upon a mountain, in the form of an amphitheatre; and the surrounding air is healthful and temperate. It is celebrated for the excellent fish caught in its vicinity, and for the manufacture of a peculiar kind of trunk made of canes, interwoven in the manner of basket-work. Tong-tchuen-foo is a fortified place, of which all the inhabitants are soldiers, and whose forefathers have followed the same profession for many generations.

This province is rich in mines of tin, iron, and lead; produces loadstone and lapis lazuli; abounds in silk, and is famous for its breed of horses. Its amber, sugar-cane, musk, and rhubarb, are highly esteemed; and it has numerous salt-pits in the mountains, from which the inhabitants draw all the salt which they use.

Yun-nan.

V. Yun-nan, *Jun-nan*, or *Yu nan*, contains 21 cities of the first class, 25 of the second, and 30 of the third. Yun-nan-foo, its capital, is celebrated for its magnificent edifices, triumphal arches, squares, gardens, and sepulchral monuments; but the Tartars, in their various incursions, have reduced the greater part of them to ruins. Its trade consists chiefly in metal; and its principal manufacture is a particular kind of satin, made of twisted silk, without flower or gloss. The other cities are not deserving of particular notice; but the province is one of the most opulent and fertile in China. Its commerce is very extensive, and consists chiefly in its own productions, gold, copper, tin, amber, and precious stones, marble, silk, linen, gums, musk, and medicinal herbs, elephants, and horses. Its inhabitants are brave, active, and robust, addicted to the cultivation of the sciences, and skilled both in agriculture and arms.

Quan-see.

VI. Quan-see, *Quoang-see*, or *Koan-see*, contains 12 cities of the first order, 25 of the second, and 73 of the third. Quei-ling-foo, situated on the banks of a narrow and rapid river, is a large city, built in the form of an ancient fortress; and is chiefly noted for the variety of birds in its district, whose plumage is so brilliant, that their feathers are frequently interwoven with silk stuffs to add to their lustre. The most remarkable of these birds is called *King kee*, or golden fowl, and is described in another part of this article. The other cities contain nothing remarkable. This province is inferior to most of the rest in wealth and extent; but it is peculiarly fertile in the growth of rice, with which it supplies the neighbouring provinces; and it contains mines of copper, tin, silver, and gold. It is celebrated for containing a singular species of tree, which, instead of pith, has a very soft pulp, from which a farinaceous substance is prepared, and converted into bread. It abounds also in a variety of curious birds, and uncommon insects, one of which produces great quantities of wax. Its wild animals are numerous, among which are found the rhinoceros, and the porcupine. The inhabitants of the western and northern districts are savage and independent mountaineers; but in the east they are more civilized, and much engaged in traffic of different kinds.

Quang-ton.

VII. Quang-ton, *Koang-ton*, or *Canton*, contains 10 cities of the first class, and a multitude of the other inferior orders. Quang-tcheoo, Quang-ton, or Canton

Canton.

the capital of the province, is situated upon a beautiful river, which communicates by means of canals with all the neighbouring provinces; and is full of merchants from all quarters of the empire, whose warehouses contain the most valuable productions of China. It is divided into three distinct cities, which, when all united, form together a regular square. The streets are long and straight, paved chiefly with cut stones, adorned at intervals with triumphal arches, and continually crowded, especially with porters, transporting the goods from place to place. They are in general very narrow; and the porcelain street, which is only from 15 to 20 feet broad, is considered as one of the largest in the city. Some of them are completely covered above, and in these the richest shops are to be found. The houses are remarkable for their neatness, consisting only of one story, and have no windows towards the street. The shops of the more wealthy merchants consist of a number of apartments in a line, opening into each other. The first, or outward apartment, is generally filled with coarse porcelain, toys, and such articles as the common Chinese are daily purchasing, and is entirely open towards the street, that passengers may easily observe what it contains. In the middle of this apartment is an opening or passage to the second, which is stored with finer porcelain, such as is purchased by European traders. Next to this, is a third vault or warehouse, filled with silks, velvets, and similar commodities. And perhaps a fourth is to be seen, in which tea, and other articles of a like nature, are arranged. On great festival days, these long narrow houses are thrown open, illuminated, ornamented with artificial flowers and trees, and provided with musicians, who occupy the most remote apartment. The river is bordered on each side with fields of rice, which appear like extensive meadows, and which are intersected by numerous canals. These are covered with boats; and upon the river, particularly, a kind of floating city may be seen, composed of barks of all descriptions, arranged in rows like streets, touching each other; and inhabited by families, who employ themselves in fishing in the waters, or in cultivating rice upon the banks. Four leagues from Canton, is the famous village of Fo-han, which is considered as the largest and most populous in the world. It is about a league in circumference, contains about a million of inhabitants, and carries on an extensive trade; but is called a village, because it is not surrounded with walls, or honoured with a particular governor. Its size and population, however, appear to be greatly exaggerated. It is described by a recent traveller, as, indeed, about a league in circumference, and as containing large well built houses; but there is only one line of buildings along the side of the river, with a very few cross streets in one or two places, which extend so short a space, that those who sail upon the river, can perceive through these openings fields behind the village. In this province, at the entrance of the bay of Canton, is the Portuguese port, called Macao, which they are said to have obtained from the Chinese, as a reward for the assistance which they afforded, in destroying a noted pirate who infested the coast. But they pay, nevertheless, a tribute of 100,000 ducats, for the liberty of choosing their own magistrates, and of living according to their own customs. There are, besides, a multitude of Chinese in the place, who are under the inspection of a mandarin; a circumstance which sometimes occasions a clashing of authorities, and renders the situation of the Portuguese governor extremely embarrassing. The town is situated upon a peninsula or rather small island, almost entirely separated from the continent by a river, and connected with it only by a small neck of land, which is inclosed by a wall. It is built in the form of an amphitheatre, upon a rising ground, and is distinguished at a considerable distance by the whitened walls of the houses. It is defended by a wall and a few forts, and garrisoned by about 150 sepoys. It contains some convents and a number of fine churches, which the Portuguese inhabitants attend on Sundays with great punctuality. On the east side is a pretty extensive quay, which affords a cool walk in the warm season, and in the vicinity of which the greater part of the Europeans have their residence. Others, however, occupy the west part of the town, from which they have a view of the port, and of a remarkable island called the Green isle, which is completely covered with trees, and finely contrasted with the arid and naked mountains, by which it is surrounded. It was upon this island, that the Jesuit missionaries first took up their abode, and passed over, during the night, to preach to the Chinese; but it is now entirely desolate, the church in ruins, and the garden laid waste.

Tchao-tcheoo-foo.

Tchao-tcheoo-foo, the second city in the province, is delightfully situated between two navigable rivers, abounding in fish, and is surrounded by fertile fields, rich in fruits, pasturage, and rice; but the air is unhealthful, and contagious distempers are very prevalent and fatal, particularly from the middle of October to the beginning of December. In its neighbourhood is a celebrated monastery of the Bonzes, which is supposed to have existed 800 or 900 years, and it was at this city that the British Embassy found young girls employed in the management of the ferry-boats. The town is about half the size of Canton, and contains about 10,000 families. The principal manufacture is nankeen stuffs, and the principal article of trade is a kind of oil, extracted from a plant named *tcha-tchoo*. This place is about 77 leagues distant from Canton, and is surrounded with walls, which are old and ruinous. Kao-tchoo-foo is likewise finely situated, in a fertile country, and is remarkable chiefly for a singular kind of stone, found in its vicinity, resembling marble. The veins have so much the appearance of trees, mountains, and rivers, that the slabs into which it is cut for tables, and other pieces of furniture, seem to have a multitude of landscapes painted upon them. Crabs, resembling those of Europe, are caught upon the coast near the town, but they are said to become petrified as soon as taken out of the water. Lien-tcheoo-foo possesses a convenient harbour, and is situated on the borders of the kingdom of Tunkin, from which it is separated by inaccessible mountains. Louitcheoo-foo is separated from the island of Hai-nan, by a narrow strait, in which pearls are said to have been formerly fished. The other cities of this province are surrounded with a rich country, and carry on considerable trade, but have nothing particularly deserving of notice. The island of Hai nan, which is within the jurisdiction of this province, is one of the largest islands of Asia. It is about 70 leagues in length from east to west, and 45 from north to south. Its capital, Kuin-tcheoo-foo, stands upon a promontory, and the ships come to anchor under its walls. Part only of the island is under the dominion of the Chinese; and the mountainous districts have still preserved their independence. These unconquered tribes used to carry on a considerable traffic with the Chinese subjects; but all intercourse with them has been prohibited. They are of a copper colour, very diminutive in stature, and deformed in person, but are extremely dexterous in the use of the bow and arrow. The island produces dragons-blood, cotton, areca, and a variety of valuable wood, of which the most esteemed is called rose-wood, on account of its smell, and is reserved for the sole use of the emperor. Among the animals which it contains, is a species of black ape, which is said to bear a most striking resemblance to the human features and form; and a number of curious birds, especially crows, with a white ring around the neck, and blackbirds of a deep blue colour, with yellow ears.

Island of Hai-nan.

The province of Quan-ton is one of the most considerable in the southern part of the empire, remarkably fruitful, and finely diversified with plains and hills. In the south, from the city of Canton to the village of San-tchoui-hien, a space of 30 leagues, the river is bordered with fine open plains, in a high state of culture; but from this place to Han hiong-foo, are lofty and romantic mountains, sometimes approaching close to the banks, and abounding in numerous quarries and collieries. The soil is dry, clayey, sandy, and of a yellowish colour, but often red, upon a bottom of clay. It produces rice, sugar, indigo, tobacco, cotton, silk; gold, tin, copper, mercury, marble, saltpetre, pearls, and precious stones; aromatic woods, particularly rose wood, eagle-wood, iron-wood, and the common kinds of tea. Besides most of the fruits of Europe, and several which belong to India, it yields some which are peculiar to itself, viz. the leetchee, and the long y-ven, the former of which is of a heating nature, and has a taste like that of a soft insipid onion; the latter is more of a cooling nature, and resembles the taste of musk. At the city of Canton the temperature is very high, especially in the months of August and September. In November, December, and January, there is a considerable degree of cold, so as sometimes to produce ice, but there is very rarely seen any snow. The coasts of this province abound in fish, oysters, crabs, and tortoises of immense size. Prodigious numbers of tame ducks are raised by the inhabitants, and are generally hatched in ovens and dunghills. They are put into small barks, carried down to the shore to feed upon shell-fish, and are collected at night by the sound of a bason, each flock returning to its own boat. The Chinese salt the flesh of these fowls, so as to preserve its original flavour; and prepare the eggs, by covering them with a coat of clay, mixed with salt. The air of this province is pure, and the inhabitants healthy, industrious, and imitative in the highest degree; but more insolent and contemptuous towards foreigners, than in any other province of the empire.

Fo-kien.

VIII. Fo-kien contains 9 cities of the first class, and 63 of the third. Foo-tcheoo-foo, its principal city, is distinguished by the beauty of its situation, the convenience of its port and rivers, the number of its learned men, and the magnificence of its bridges. Tsuen-tchoo-foo is nearly equal to the last-mentioned city in respect of beauty and advantages; but is particularly remarkable for a fine temple and a singular bridge. The former is adorned with two lofty towers, seven stories high, built of stone and marble, and having a gallery at each story, around which a person may walk, and view the beauties of the city and country. The latter, which is both of an extraordinary size and singular construction, is built of a blackish-coloured stone, and instead of arches, has about three hundred stone pillars, formed with acute angles on their sides, to break the force of the stream. Five stones, of equal size, laid transversely from one pillar to another, form the breadth of the bridge, and each of these stones is said to be about 18 yards in length. Of these there are 1000, all of the same size and figure. On each side of this bridge are buttresses of the same stone, with figures of lions, &c. on the tops, and in the middle of the bridge is built the castle of the city. Kien-ming-foo is mentioned in the Chinese history as having sustained two sieges at the conquest of the country by the Tartars; and its inhabitants, obstinately refusing to submit to the victors, were all put to the sword. Yen-ping-foo is built on the side of a mountain, and defended by the high hills in its vicinity, and so situated, that all the boats of the province must pass close by the foot of its walls, upon the river Min-ho. Tchan-tcheoo-foo, a place where the missionaries pretend that they found some vestiges of the Christian religion, and which carries on a very extensive trade with the isles of Emoy, Pong-hoo, and Formosa. It is situated upon a fine river, over which there is a large bridge of 36 arches, and so broad as to admit of shops on each side, which are stored with the richest merchandize of China and India. The small island of Emoy, or A-mwy, or Hia-men, is in the province of Fo-kien, contains a magnificent pagoda, sacred to the god Fo, and has an excellent harbour, capable of containing some thousands of vessels, with so great depth of water, that the largest ships may anchor close to the shore without danger. It was much frequented by European traders at the beginning of the last century, and the Chinese emperor kept in it a garrison of six or seven thousand troops. The isles of Pong-hoo, which are also in this province, form a kind of Archipelago between Emoy and Formosa, but they are little better than mere rocks or sand-banks, and the inhabitants must import every necessary of life. They furnish, however, convenient harbours to the ships visiting Formosa; as that island possesses no port, which is capable of admitting any vessel that draws above eight feet of water.

Island of Emoy.

The province of Fo-kien, though not of great extent, is very rich and flourishing. Its climate is warm, and its air healthful. Its mountains are numerous, but covered with forests, or cut into terraces, and carefully cultivated. Its productions are copper, tin, mercury, steel, iron, musk, crystal, silk, black-teas, linen and cotton stuffs, sugarcandy, a variety of wood, excellent paper, and pencils. It contains precious stones, and gold and silver mines, but these are not allowed to be opened. It carries on a very extensive trade with Japan, Formosa, Java, Siam, Camboya, and the Philippines; and its vessels of all descriptions are exceedingly numerous. It was formerly a separate kingdom, and its inhabitants still speak a great variety of dialects.

Tche-kiang.

IX. Tche-kiang, or *Tse-kian*, contains 11 cities of the first class, 72 of the third, and 18 fortresses, which may be accounted as towns. Hang-tcheoo-foo, the capital of the province, is regarded by the Chinese as an earthly paradise, and is one of the largest, richest, and best situated cities in the empire. It is said to be four leagues in circumference, exclusive of its suburbs; and its inhabitants are computed at one million, of which one thousand are employed in the manufacture of silk. Its streets are narrow, but well paved with broad flag-stones. They are full of very large shops and warehouses, stored with English broad cloths and peltry, in some of which not less than ten or twelve persons are serving behind the counter. The shops of the apothecaries and perfumers were particularly noticed by M. De Guignes, as finely ornamented; and he observed also numerous triumphal arches, adorned with figures, which had the appearance of being cut in stone, but which he concluded, from one that was broken, to be formed of some composition. A small lake, called See-hoo, washes its walls on the western side, and adds greatly to the beauty of the place. The water of this lake is clear as crystal, full of eels and other kinds of fish, and its banks covered with flowers. Open galleries, supported by pillars, and paved with large flag-stones, are erected along its sides for the convenience of walking; and causeways, cased with cut stones, traverse the lake in various directions, having numerous openings, covered with handsome bridges for the passage of the boats. In the middle of the lake are two islands, in which a temple and other houses of entertainment are erected for the reception of those who amuse themselves in the place. "Its natural and artificial beauties," says Mr Barrow, "exceeded every thing we had hitherto an opportunity of seeing in China." The surrounding mountains are lofty and picturesque; the vallies clothed with trees, especially the camphor-tree, tallow-tree, and arbor vitæ, (the first a bright green, the second purple, and the third a deep green colour), and varied and romantic sepulchres are seen in avenues among the trees, surrounded with cypress. Parties of pleasure in barges are frequently formed on the lake, but few females, except those of loose character, join in those excursions. Kia-king-foo, is remarkable for its fine streets, which are furnished with beautiful piazzas to shelter the passengers from the sun and rain. Hoo-tcheoo-foo, is situated on a lake of the same name, and is celebrated for the immense quantity of silk, manufactured within its walls. Ning-po-foo, called by the Portuguese Li-ang-po, or Liampo, is an excellent sea-port, on the east coast of the province, opposite to Japan; and about 20 leagues from the town, is the island of Tcheoo chan, where the English landed upon their first arrival in China, in the year 1700, as they were not able to find their way through the numerous islands on the coast to the port of Ning-po. The town is famed for its silks, of which it sends great quantities to Batavia, Siam, and particularly to Japan. Chao-hing-foo, is situated in an extensive plain, and in its vicinity is a very ancient sepulchral monument, which the Chinese consider as the tomb of the Great Yu. The inhabitants of this town and its district are said to be superior to most of the Chinese in their acquaintance with all the chicanery of the laws, and are generally preferred as secretaries to the higher mandarins. Tchu-tcheoo-foo, may be mentioned on account of the pine-trees, which grows upon a mountain in its neighbourhood to so extraordinary a size, that one of them will contain 40 men in the hollow of its trunk.

Lake See-hoo.

The province of Tche-kiang, extends from 28° to 34½° north latitude; and its mean temperature in the middle of November, was found to be from 56° at sunrise to 62° at noon. In the space of fifty leagues to the north of Hang-tcheoo-foo, the soil is clay upon a bottom of potters earth, the country level, and the mountains commence only in the environs of the city. For the space of sixty leagues, as far as to Tchan chan-hien, it is more or less mountainous, the soil sandy and reddish, like the stones on the hills. On the side towards Kiang-see, for the space of twelve leagues, it is mountainous, and the soil of a clayey nature. The province in general is in a state of high cultivation, and its population is immense. Its climate is healthful, its plains well watered, and its canals in good repair. On account of its maritime situation, its extent and population, it is one of the most considerable provinces in the empire; and was formerly the residence of some of the emperors. Its principal trade consists in silk stuffs, of which those kinds, that have gold and silver interwoven, are the most esteemed. Great numbers of silk worms are of consequence reared in the province; and whole plains are covered with dwarf mulberry trees for their support. These trees are purposely checked in their growth; as it is found by experience, that the worms, which feed on the leaves of the smallest trees, yield the finest silk. Notwithstanding the immense quantities exported to the other provinces of the empire, to Japan, Europe, and the Philippines, so much still remains, that a complete suit of silk may be purchased in this province as cheap as one of the coarsest woollen in Europe. The province produces, also, different kinds of wood, especially bamboo and the tallow tree; and mushrooms grow in such abundance, that they are pickled and dried; in which state they may be preserved a whole year, and when soked in water, become as fresh as at first. The province yields also, indigo, and is celebrated for the excellence of its hams. The inhabitants are said to be extremely superstitious, but they are lively, mild, and polite to strangers.

Kiang-nan.

X. KIANG-NAN, or *Nan-kin*, may be considered as the second province in the empire, and is divided into two parts, each of which has a distinct governor. It contains fourteen cities of the first class, and ninety-three of the second and third, besides innumerable towns and villages of considerable size and population. Kiang-

Nankin.

ning-foo, or Nankin, the capital, is said to have been, in former times, one of the most flourishing and splendid cities in the world, and is still the largest city in China. It is of a very irregular form, and is built upon several mountains, and its walls are said to be five and a half leagues in circumference; but it is spoken of in the most extravagant style by the Chinese, as having been, in ancient times, fifty and even ninety miles in compass; or, as they express it, so large, that, if two horsemen had set out in the morning, at one of the gates, and galloped round it in different directions, they would not have met till the evening. It was, at one time, the residence of the emperor, and was then called Nan-kin, or the southern court; but, in all public acts, it is now named Kiang-ning. Nearly one third part of it is now deserted by the inhabitants; and scarcely a vestige remains of the magnificent palace, observatory, temples, and monuments, which it once contained. Its gates are still beautiful, and a few of its temples are in good preservation, among which is one, called the Porcelain Tower, about 200 feet high, which is divided into nine stories, to the first of which there is an ascent of forty steps, and between each of the others a stair of twenty one steps. Near to Nankin is the broad and deep river Yang-tse-kiang, which furnished a commodious port to the city, but the navigation of which is now greatly neglected. In the months of April and May, great quantities of excellent fish are taken in this river, in the vicinity of the town; and, being covered with ice, are transported in boats to the court at Pekin. The streets of Nankin are narrower than those of most other Chinese cities; but are finely paved, and much more free from dust and dirt, than those of Pekin. It contains many learned men, valuable libraries, and extensive booksellers' shops; and its paper, ink, and other materials for writing and painting, are said to excel all others in the empire. The country around it is richly adorned with gardens, orchards, villas, &c.; but the most remarkable object in its neighbourhood is a wood of lofty pines, which is about twelve miles in circumference; and in the centre of which is a mound, rising above the forest, covered with temples and sepulchral monuments. Soo tcheoo foo, is the second city in the province, and one of the most agreeably situated in China. It is compared by Europeans to the city of Venice, with this difference, that the one is built upon the sea, and the other intersected by canals of fresh water. Its streets are narrow, and its shops present nothing remarkably striking. It is of great extent, and its walls inclose large portions of cultivated ground, with numerous fields and isolated buildings. It carries on a considerable commerce with Japan; and its brocades and embroideries, which are the principal manufactures of the place, are in great request, as being at once the finest and cheapest in the empire. The neighbouring country is delightful, the soil fruitful, the air temperate, the people polite; and the whole spot is called by the Chinese, the paradise of the world. Its inhabitants appeared to Mr Barrow to be more chearful, contented, and better clothed, than those of any other town that he had seen in China. The ladies, he observed, were dressed in petticoats instead of trowsers, which last was the costume in the northern provinces; and this city is one of the places where young women are carefully educated in singing, music, and dancing, to be sold as concubines to the higher mandarins. To the west of the city is a range of mountains covered with wood, and along their base is the extensive lake Tai hoo, famed for its fine fish and picturesque scenery. Tchan-tcheoo-foo, is situated near the canal, through which all the boats from Soo-tcheoo foo to Nankin must pass. It is celebrated for the excellence of its water, which is said to give a peculiarly pleasant flavour to tea, and for a kind of earthen ware, made in the district, which is supposed to have a similar effect, and is therefore preferred by the Chinese to the finest porcelain. Hoai-ngan foo, is remarkable chiefly for its situation in a marsh, and stands upon ground lower than the canal which surrounds it. It is thus in continual danger of inundations (to guard against which, it is inclosed by a triple wall;) but notwithstanding its hazard from the waters, it is sufficiently populous and full of trade. Yang tcheoo-foo, is a city of considerable extent, intersected by numerous canals, and provided with a multitude of bridges. The quay is formed of layers of straw and earth; and the place is crowded with boats, a great proportion of which are employed in conveying salt, which is the staple commodity of the city. There are several pagodas in the town and its neighbourhood; but, though the descriptions given of it by the Jesuit writers, are highly magnificent, M. De Guignes pronounces the house of the Hoo-poo to be the only building worthy of notice. It bears the marks, however, of great antiquity; and contains numerous ruins, overgrown with moss and creeping plants, which indicate that its grandeur has greatly decayed. In its neighbourhood, is one of those royal residences, which are provided for the accommodation of the emperors, as they pass through the empire; and which was built by the Emperor Kao-tsoo of the dynasty of Sooee. It is named Kao-min-chee, and consists of a tower, close by a pagoda, and surrounded by buildings, pavilions, and gardens. The tower is described by De Guignes as one of the finest that he observed in China. It consists of five stories, with a covered gallery around the outside of each, and with sixteen windows in each story. It has eight sides, and eight gates, white walls, and the wood-work painted red, a large tree on the top, surrounded by a spiral of iron, and surmounted by a gilded ball terminating in a point. Hoei-tcheoo-foo, the most southern city of the province, and one of the richest in the empire, has mines of gold, silver, and copper, in its adjacent mountains; and its inhabitants, who are temperate, frugal, and enterprising, are famed for preparing superior tea, varnish, and engravings. Fong-yang-foo, is situated on a mountain, which overhangs the Yellow river; and incloses several fertile little hills within its walls. It was the birth-place of the Emperor Hong-voo, the chief of a dynasty, who designed to have made it the seat of his court, and gave it its present name, which signifies "the place of the Eagle's splendour;" but finding that the inequality of the ground, and the scarcity of fresh water, would prove insuperable inconveniences, he changed his purpose, stopped his intended improvements, and removed his residence to Nankin. Three monuments of great extent and grandeur still remain, viz. the tomb of the Emperor's father, a magnificent temple of the god Fo, and a tower in the centre of the city, of an oblong form, and about 100 feet high.

Island of Tsong-ming.

To this province belongs the island of Tsong-ming, which is separated from the continent by an arm of the sea, about six leagues broad, and which was formerly a mere sandy desart, to which criminals were banished, and left to their own resources. By the exertions of those persons, and the assistance of a few poor Chinese families, it was at first brought into some degree of cultivation, and is now a populous and tolerably fruitful spot. Its principal production is salt, which is extracted from a kind of gray earth in the following manner; the earth is first smoothed and raised in a sloping form, that the water may not settle upon it; and when the sun has dried its surface, it is removed and laid in heaps, which are carefully beaten on every side. It is then spread on large tables, a little inclined, and fresh water is poured upon it, which, as it runs off, carries along with it the particles of salt into a small canal, by which it is conveyed to a large earthen vessel. The earth, which has thus been freed from its salt, is thrown apart till it becomes dry, when it is again pulverized, and spread over the soil from which it was taken, when in a short time it is again impregnated with saline particles, which are again extracted as before. The salt-water, thus procured, is then boiled by the women and children, and put into large iron basons, which they continue to stir with an iron spatula, till the aqueous parts be evaporated. The extent of this island is about twenty leagues in length and five or six in breadth. It has only one city, which is of the third rank; but it is covered with villages, and intersected with canals.

This province extends from 31° to 34½° north latitude; and its mean temperature, from the 30th of October to the 9th of November, was found to be 54° at sun-rise, and 66° at noon: The sky at the same time was uniformly clear. The country is in general level, except in the neighbourhood of the river Hoang-ho. The soil, in the western part of the province, is a dry reddish clay; the banks of the river are a yellowish clay, and the eastern division is chiefly light and sandy, but towards the south-east there is more of a good clay, and often a black fat earth. It is much intersected by rivers and canals; and, being thus capable of being flooded in dry seasons, it is extremely valuable and fertile. Every part of it, also, has easy communication with the Yellow Sea, by means of the two great rivers Hoang-ho and Yang-tse-kiang; and it is thus considered as the central point of the home trade of China. Its cities are large, populous, and flourishing; and it is one of the most extensive, commercial, and wealthy provinces in the empire. Its silk stuffs, japanned ware, ink, and paper, are greatly valued; and in one village alone, with its dependencies, it is reckoned that 200,000 persons are employed in weaving cotton cloths. There are numerous salt-pits on the coast, which yield an immense revenue to government. The inhabitants are civil, ingenious, and apt in the acquisition of learning; and many of them have become eminent in the literature of the nation.

Shan-tong.

XI. SHAN-TONG, *Chan-tong*, or *Xan-tong*, contains 6 cities of the first class, and 114 of the second and third. Tsee-nan-foo, the capital, situated on the south of the river Tsee, is large and populous, and is much honoured by the Chinese, on account of its having been the residence of a long succession of sovereigns, whose tombs on a neighbouring mountain present a very striking view from the city. Kio-feoo is celebrated chiefly as having been the birth-place of the celebrated Confucius, or Kong-foo-tsé. Lin-tchin-tcheoo, situated on the great canal, is a place of much trade, and contains a remarkable octagonal tower, eight stories high, covered on the outside with neatly painted porcelain, and encrusted in the inside with variegated marble. All its cornices and projections are furnished with small bells, which, when moved by the wind, yield a pleasing sound; and in the highest story is placed an idol, of gilt copper, to which the tower is consecrated. Tsin-tcheoo-foo is celebrated for its immense traffic in fish, of which so great a quantity is caught in its vicinity, that the sale of their skins is said to yield a very considerable profit; and also for a yellow stone, produced in the belly of the cows in its district, which is as large as a goose's egg, brittle as crayon, and used in medicine. To this province belong several small islands, the greater part of which are provided with good harbours, which afford a convenient shelter to the Chinese junks that sail to Corea and Leao-tong.

This province extends from 34½° to 38° north latitude; and its mean temperature, from the 19th to the 29th of October, was found to be about 52° at sun-rise, and 70° at noon, with a constant clear and cloudless sky. The country is in general level; but towards the south it is full of mountains and swamps. The soil is a dry sand, of the colour of ashes, or rather a collection of mud and slime deposited by the rivers, and scarcely containing a single pebble; and there are large tracks of marsh and moss, which are inhabited only by a few miserable looking fisher-tribes. Very little rain falls in the province; but, besides its many lakes and rivers, which are highly useful in fertilizing its plains, it is traversed by the great imperial canal, which adds greatly to its wealth; as all the vessels, which transport such immense quantities of provisions and merchandise to Pekin, must thus pass through its territory. Besides the common silk worm, there is found in this province another insect, resembling the caterpillar of Europe, which produces a coarser kind of silk, of which however are made very strong and durable stuffs, which are in great request throughout China. It abounds also in grain of all kinds, especially wheat, rice, and millet. The inhabitants are accounted the keenest sportsmen in the empire, and are very strong and hardy. It is frequently infested by locusts, and the mountainous districts are much frequented by wolves.

Ho-nan.

XII. Ho-nan contains 8 cities of the first class, and 102 of the second and third, with a number of castles and fortified places. Cai-fong-foo, the capital, is situated at the distance of two leagues from the river Hoang-ho, upon ground which is lower than the river, and where strong dikes, to the extent of 30 leagues, were erected by government to prevent inundations. When it was besieged in 1641, by an army of 100,000 rebels, the general, who was sent to its relief, formed the design of drowning the enemy by opening these dikes. His plan was successful, as far as related to the opposing army; but the inundation was so sudden and violent, that the city also was overflowed, and 300,000 of the inhabitants destroyed. It is conjectured from its ruins to have been about three leagues in circuit; but though it has been rebuilt, its size is very limited, and it is distinguished from ordinary cities only by the extent of its jurisdiction. Tchang-te-foo, one of the most northern cities of the province, is remarkable for a fish in its vicinity which resembles a crocodile, and the fat of which is of so very singular a nature, that when once set on fire, it is scarcely possible to extinguish the flame; and for a mountain in its district, so steep and inaccessible, that, in time of war, it used to afford a secure asylum to the inhabitants. Ho-nan-foo, situated in a mountainous region, between three rivers, was formerly called by the Chinese the Navel of the Earth, because it is supposed to be exactly in the centre of their empire. It is famed for an ancient tower in one of its villages, which is considered as having been the observatory of the celebrated Chinese astronomer Tcheoo-kong, who is said to have lived 1000 years before Christ, and is affirmed by his countrymen to have invented the mariner's compass. They still show an instrument, which he is supposed to have used for finding the length of the meridian shadow, in order to determine the latitude. This province is situated nearly in the centre of the Chinese empire, and, in reference to its situation and beauty, is called Tong-hoa, or "the middle flower." The ancient emperors, invited by the mildness of the climate, and the beauty of the country, generally resided in it part of the year. Its abundant fruits, however, rich pastures, plentiful crops, cheap provisions, together with the effeminacy of its inhabitants, have prevented the progress of commerce in its territories. The eastern part is very flat, and finely cultivated, so as to appear like one immense garden; but towards the south-west it is more mountainous, and covered with forests. Besides numerous streams and fountains, it is traversed by the river Hoang-ho; and has a fine lake within its territories, the water of which is said to impart a peculiar lustre to silk, and the banks of which are therefore covered with the manufactures of that article. It produces fruits and grain of all kinds, silk, cinnabar, loadstone, talc.

Hoo-quang.

XIII. Hoo-quang, or *Hoo-koang*, is divided by the river Yang-tse-kiang into two parts, northern and southern; and contains 15 cities of the first class, 114 of the second and third, exclusive of numerous fortresses and villages. Voo-tchang foo, the capital, situated on the river Yang-tse-kiang, is the great resort of the commercial people of China. Its ports are crowded with vessels, sometimes covering the river for the space of two leagues; and every branch of trade is carried on within its walls. It is celebrated for its plentiful crops of fine tea, its manufacture of bamboo paper, and the beautiful crystals which are found in its mountains. Tchang-tcha-foo, the principal city of the southern division, is situated upon a large river communicating with an extensive lake; and is remarkable only for a festival, instituted in one of its dependent cities, in honour of a mandarin, one of its governors, which is still solemnized with great splendour throughout the empire, by sports, feasts, and combats on the water; but the latter part of the amusement, owing to the accidents with which they were frequently attended, have been in a great measure prohibited.

This province is generally level, and well watered by lakes, canals, and rivers. Its soil is rich and fertile in a high degree; and it is called the granary of the empire. It produces great quantities of rice, excellent cotton, paper, wood, crystal, talc, iron, tin, vitriol, mercury.

Koei-tcheoo.

XIV. Koei-tcheoo, or *Quei-tcheoo*, one of the smallest provinces of China, contains 10 cities of the first class, and 38 of the second and third. Koei-yang-foo, the capital, is said to have once been an imperial residence; and remains of temples and palaces still prove its ancient magnificence. Some of the other cities are situated in fertile vallies, and on the banks of pleasant rivers; but the province is, in general, a kind of desert, covered with inaccessible mountains. Its ancient inhabitants, a tribe of savage mountaineers, still preserve their independence; and the Chinese colonies on the lower grounds, obliged, by the dread of these depredators, to keep near the fortified places, are prevented from improving the soil to any great extent. All attempts to subdue these plunderers, and to secure the cities from their incursions, have been attended with very partial success. It is regarded, in short, as the Siberia of China, and its mandarins are generally disgraced nobles, whose family connections or former services prevent them from being altogether discarded from office. It has mines of gold, silver, copper, and quicksilver; and produces a species of hemp, which is made into cloth for summer dresses. It furnishes the best horses in China, numbers of cattle and hogs, and particularly wild fowl of exquisite flavour.

Kiang-see.

XV. Kiang-see contains 13 cities of the first rank, and 78 of the second and third. Nan-tchang-foo, has great trade, chiefly in porcelain, which M. De Guignes describes as sold remarkably dear; and is so much frequented, that Mr Barrow calculated, at the time of the British embassy passing it, that, independent of innumerable small craft, 100,000 tons of shipping lay around it. Its streets, however, as observed by M. De Guignes, were narrow and dirty, and few of its shops richly stored. In its neighbourhood is situated a celebrated temple, with a large well belonging to it, full of great snakes, which the priests exhort the people to worship as the children of dragons, which, if not appeased by sacrifice and offerings, would destroy the whole world. It is affirmed as a natural fact, that the appearance of these snakes upon the surface of the water always prognosticates rains and inundations, a circumstance which assists to support the superstitious reverence which is paid to them. Jao-tcheoo-foo, or Zhao-tcheoo-foo, situated on the northern bank of the lake Po-yang, is particularly celebrated for the beautiful porcelain, which is manufactured in a village of its district, called King-te-tching. This village is as populous as the largest cities in China, and is said to contain a million of inhabitants, crowded together in long narrow streets. It stretches along the banks of a fine river, which forms a harbour about a league in circumference, which is sometimes lined, throughout its whole extent, with a triple row of barks. All the provisions, which it requires, are brought from a distance; and even the wood, which is consumed by the furnaces, is carried about 100 leagues. It is, nevertheless, a general asylum to poor families; as children and invalids

Topography.

find employment suited to their strength, and even blind persons gain a subsistence by pounding the colouring materials. It is said to contain about 500 furnaces, all employed in making porcelain, the flames and smoke of which give it the appearance at night of a city on fire. Strangers are not permitted to lodge in the town, but must sleep in the boats, unless they have friends among the inhabitants, who become security for their conduct; a regulation which is supposed necessary in a place, which is so full of valuable articles, and so likely to attract plunderers. Lin-kiang-foo, situated on the banks of the Yu-ho, in a healthful climate and good soil, is so much deserted, that the Chinese have a saying, that one hog would maintain the whole of the inhabitants for two days. But one of its villages is a considerable market for drugs, and its neighbouring mountains yield great quantities of oranges, on account of which articles it is held in some repute. Kang-tcheoo-foo, a populous and flourishing city, situated at the confluence of two rivers, has a bridge of 130 boats, joined together by iron chains, and upon this bridge is built the custom-house. Two or three of the boats are left moveable, in such a manner as to afford an opening, when necessary, for vessels to pass up or down. In the neighbouring country is found abundance of those trees, which yield the varnish used in japanning, and which are supposed to be the *Rhus Vernix*.

This province extends from 28° to 30° of north latitude; and its mean temperature, in November, was found to be from 56° at sun-rise, to 62° at noon. It is full of rivers, lakes, and marshes towards the north; but rather mountainous in the south. The soil is, in general, a dry reddish, occasionally yellowish, sand, upon a bottom of clay; and in some spots was observed a depth of six feet of vegetable earth; but around the Po-yang lake, which is in this province, the country is a continued marsh for an immense extent. It produces excellent rice, with which several barks are annually loaded for the use of the court; but wheat and sugar-cane are the chief crops, the latter of which is peculiarly juicy, and has joints from six to nine inches in length. Though sufficiently fertile, it is so very populous as to be unable to supply its inhabitants, who are, on that account, extremely economical, and accustomed to very spare diet. Hence they are exposed to the raillery of their neighbours; but they are said to be very acute and intelligent, and readily rise to the higher dignities in the state. Its mountains are covered with medicinal herbs; and contain also gold, silver, iron, lead, tin, vitriol, alum, and crystal. It furnishes also, as articles of trade, tallow, paper, and varnish. The women of this province are more robust than those of most other parts of China; are strangers to the custom of cramping the feet, and are much employed in the labours of the field. When a Chinese farmer, therefore, is in quest of a working wife, he goes to purchase in Kiang-see.

Number of towns, &c. in the empire.

According to the flaming statements of the Chinese, the whole cities of these 15 provinces amount to the number of 4402, divided into two classes, civil and military; the frontiers and sea coasts are defended by 439 castles, well fortified, and covered by 2920 towns, many of which are equal in population and extent to the walled cities; while the villages, scattered over the interior, are declared to be innumerable. There are also, according to the same authorities, 1145 royal hospitals, or lodging places, for the officers and servants of the court; 1159 triumphal arches, erected in honour of kings and heroes; 208 monuments, dedicated to the memory of females, who have been distinguished by the virtues of their sex; 272 libraries, continually open to the learned; and in almost every city or town, schools and colleges, established by Confucius, or founded in honour of his name.

Topography.

Tributary states.

The other parts of the Chinese dominions and tributary states, viz. Chinese Tartary, the island of Formosa, the kingdoms of Corea, Tunkin, Cochin-china, Thibet, Hami, and the isles of Lieoo-kieoo, will form the subject of separate articles. But we may here shortly notice those distinct and almost independent tribes, who reside within the limits of the Chinese empire, and may, indeed, be classed among its subjects; but who are still so different, in many respects, from the other inhabitants of the country, as to require a separate description.

Sifans.

1. The SIFANS or *Toopans*, whose country is situated to the west of the provinces Chensee and Se-tchooen, between the 30° and 35° of north latitude, and forms a continued ridge of mountains covered with snow, even in the month of July, inclosed by the rivers Hoang-ho on the north, Ya-long on the south, and Yang-tse-kiang on the east. They are divided into two tribes, called by the Chinese, from the different colours of their tents, the black and the yellow Sifans. The former are a miserable uncivilized people, who live in small bodies, governed by petty chiefs, who are all dependent upon one as their head. The latter are ruled by a family of princes, or rather priests of the god Fo, who have each a separate district; and the oldest of whom is styled Lama, and is distinguished by a yellow dress. The payment of certain honours, and of the dues to the idol divinity, which are not very burdensome, is all that they exact from their subjects. A few of the Sifans have houses of earth or brick; but the greater part live in tents, in small hamlets of five or six families. Their chief occupation is the rearing of their flocks, and a traffic in rhubarb, which their country produces in great abundance. Some of their rivers wash down particles of gold among the sand, of which they form small vases and statues; and with the general use of which, they seem to have been long acquainted. They were once, it is said, a powerful nation, whose dominions extended to the boundaries of Cachemire, and often proved formidable enemies to their Chinese neighbours. But since the year 1227, they have been confined within their native mountains, and have sunk back into their original barbarism. They still maintain a proud and independent spirit, acknowledging, with reluctance, the supremacy of the Chinese emperors, and seldom obey the edicts of the mandarins; but the government of China connives at their disaffection; and endeavours, by mild measures, to preserve in some degree of subjection, a people, whose frightful mountains would enable them to defy all attempts to reach them by force.

Lo-los.

2. The LO-LOS, who are dispersed through the province of Yun-nan, were formerly governed by their own sovereigns; but submitted to the Emperor of China, upon condition of enjoying for ever the honour of mandarins, with which office accordingly the head of every family is invested. They are ruled by princes of their own nation, who govern them in a very despotic manner, and have the power of punishing with death, without the concurrence of the Chinese viceroy. These princes have numbers of officers attached to their respective services, and can appoint the commanders of their own troops. These people are a well made and very hardy race. Their dress consists of plain drawers, a cotton vest, which reaches to the knee, a straw hat, and sandals on their feet, but no covering to their legs. The women wear a long robe, covering the whole body, and descending to the feet, above which is fastened a small cloak reaching to the girdle; and in this dress they appear on

horseback, at visits, marriage ceremonies, &c. attended by their female servants, mounted in like manner. Their princes dress in the Tartar style, and generally make use of silk stuffs. The Lo-los have a language of their own, and their mode of writing resembles that of the Bonzes of Pegu, who have acquired the favour of the most powerful families in the western part of Yun nan, and introduced among them the religious worship of their own country.

Miao-tse.

3. The Miao-tse, or *Mountaineers*, is a name given to several tribes, who differ in some respects from each other; but who, like the Lo los, are governed by their own princes, who have a royal household, officers, and militia, of their own appointment. They are a half civilized people, dispersed through the mountainous districts of the western provinces, and often make predatory incursions upon the level country. They are armed with bows and half pikes, and are very dexterous horsemen. Their horses are remarkable for the agility with which they climb the steepest mountains, and are highly valued in China. Those who are candidates for any office of command among them, are required to prove their horsemanship, by riding at full speed down the steepest places, and by clearing at one leap ditches of considerable width, in which fires are kindled. The Chinese consider these people as sufficiently subdued, if they can confine them within their mountainous districts; and for this purpose, they have erected around them numerous castles and fortresses strongly garrisoned. Those, who inhabit the province of Koei-tcheoo, are rather more civilized than the other tribes, dwell in houses built of brick, form themselves into villages, cultivate the soil, manufacture carpets and coarse muslin, and float considerable quantities of timber down their rivers, which they exchange with the Chinese for oxen, cows, buffaloes. Their ordinary dress is a pair of trowsers, and a kind of jacket which laps over the breast. They wear a strong and weighty breast plate of hide, covered with laminæ of steel or copper. Those who inhabit the southern part of the province of Hoo-koan, are equally independent as the rest of their nation, but profess to acknowledge the authority of the mandarins. They are remarkably hardy and active, and run bare-footed over the roughest grounds and steepest rocks. Their young women wear a singular kind of head-dress, consisting of a small board, about a foot in length and five or six inches in breadth, over which they spread their hair, and fix it to the wood with wax. This wax is melted at the fire, and the hair combed, cleaned, and arranged anew, three or four times a year. Those, who reside in the more central parts of this province, are in a great measure subject to the Chinese, whose manners they have entirely adopted, and from whom they are distinguished only by a peculiar covering of the head. The whole Miao-tse race are regarded by the Chinese with the utmost contempt, and are represented by them as a barbarous set of banditti; but the missionaries always speak of them as an active, laborious, civil, and honest people. On their part, they have an equal detestation of the Chinese, whom they consider as severe and oppressive masters, who would be unable to subdue them if they were united, but who contrive to keep them shut out from communication with one another. These tribes, after having preserved their independence almost 2000 years, were at length reduced to a state of subjection by the defeat of their two most formidable states on the frontiers of Se-tchuen, and Koei tcheoo. Having committed some devastations upon the territories in their neighbourhood, about the year 1752, the Emperor Kien-long, resolved to accomplish their subjugation, and, after a tedious war of 25 years, they were finally reduced in 1776, by the skill and perseverance of the Chinese general, Akouee. The Miao-tse defended themselves with determined valour, and even their women are said to have fought with the most obstinate fury, of which the following instance has been recorded. A party of Chinese soldiers, during the space of two months, had employed, in vain, every method of force and stratagem to gain possession of a small fort on the summit of a high rock. One morning, about day-break, their guard was alarmed by the sound of footsteps, as of a person treading with great caution; upon approaching silently the place from which the noise proceeded, they perceived something indistinctly in motion; and some of the most active, having scrambled up the rock, by the assistance of cramp irons on their feet, discovered a woman drawing water. Having seized and questioned her, particularly with regard to the strength of the garrison, which had made such resistance, "I," she replied, "I alone; but being in want of water I came hither, not expecting to meet with you." She then pointed out to them a secret path, by which they reached the fort, of which she had been the sole defender, sometimes by firing her musket, and at other times by rolling down fragments of the rock, upon those whom she observed attempting to ascend.

Jews.

4. The Jews, of whom a numerous colony, according to their own account, and to the records of the Chinese, entered China about the period of Alexander's expedition to India; and are supposed to have been a part of the followers of his army. They reside chiefly in the provinces where silk is manufactured, especially in the city of Hang-tchoo-foo; and it is conjectured to have been chiefly owing to their skill in preparing that article, perhaps to their having originally introduced the use of it into the country, that they have recommended themselves so much to the notice of the government, as to have obtained a variety of privileges, and to be allowed even to intermarry with the natives. In one of their synagogues the missionaries found a copy of the Pentateuch, and some other fragments of the sacred writings; but except their rabbis, they have now no knowledge of the Hebrew language; and had never heard of any other Jesus than the son of Sirach. Many of them are said to have forsaken their own religion, at least in appearance, and to have arrived at high offices in the Chinese government.

History.

The knowledge of the origin, history, and condition of this extensive and extraordinary empire is still extremely imperfect and uncertain. It was only at a late period that the nations of Europe became acquainted even with the existence of the country; and even then, the peculiar nature of the language, and the careful exclusion of foreigners by the government, prevented, and still in a great measure prevent, that degree of intercourse with the people, which is necessary to procure correct information of their manners, and free access to their historical records.

Origin.

With respect to their origin, it has been conjectured, from the coincidence between several of their tenets and the mythology of the ancient Egyptians, that they are descended from an Egyptian colony; but, on the other hand, it is asserted, that there is no resemblance between the Chinese and the Egyptian features, and no appearance of the former having become, in later times, a mixed race. It is conceived, that the vestiges of Greek and Egyptian superstitions, still found in China, may be ascribed to the wanderings of those exiled Greeks and

Egyptians, whom Ptolemy Physicon expelled from Alexandria, and who travelled eastward to seek a refuge among the Persians and Indians. There is perhaps a still greater analogy between many of the Chinese nations and customs, and those of the Hindoos and other Indian nations; as, for instance, in their predilection for the number nine, in their observance of solstitial sacrifices, in their practice of making offerings to the *manes* of their ancestors, in their dread of leaving no offspring to perform their funeral obsequies, in their manner of dividing the zodiac, and of distinguishing eight instead of four cardinal points of the compass. But, notwithstanding these moral coincidences, as they may be called, there is understood to be strong physical evidence of the Chinese being descended from a stock entirely distinct from the Egyptian, Greek, or Indian; and their peculiar features are represented by intelligent observers, as decidedly of what is called the Tartar cast, which is found to prevail on the continent of Asia, from the tropic of Cancer to the Frozen Ocean, appearing first in Bootan, and spreading thence over the peninsula of Malacca, and the multitude of Malay and Japan islands; and which is conjectured to have been transmitted, with little intermixture, from the earliest tribes of mankind after the deluge.

Antiquity.

The Chinese themselves, indeed, have advanced the most extravagant claims with regard to the antiquity of their nation; and pretend to trace back their history to a period, far anterior to the Scripture date of the deluge, and even of the creation. Some of them have ascended in their flight more than ninety millions of years before the Christian era; and till very recently, the greater part of European authors were disposed to regard them, as having possessed a stable and civilized government, about 3000 years before the birth of Christ. It has been supposed, that Tartary, as being the highest ground on the globe, was the seat of the family and descendants of Noah immediately after the deluge; that Moses, by Mount Ararat, does not mean any particular mountain of that name, but only the highest mountain on the face of the earth; that the ark, therefore, rested on some of the elevated tracts inhabited by the Eleuths, from which flow a number of large rivers corresponding to those mentioned in the Scripture history, namely the Solenza, which falls into the lake Baikal and the Frozen Ocean, the Amour, which carries its waters eastward to the gulf of Tartary, and the two great rivers of China which flow southward; that Noah may be conceived to have followed the course of these last mentioned rivers, as leading to a fertile and open country, and that he was thus the actual founder of the Chinese monarchy, and the same with the Fo-hee or Foo shee of their history. This opinion, which was proposed by the learned Shuckford, is very keenly and ingeniously supported by the authors of the *English Universal History*; and their argument is founded upon a fact mentioned in the Chinese annals, as having taken place in the reign of Yao, their seventh monarch from Fo-hee, namely, that "the sun did not go down during the space of ten days." This they conceive to be the miracle recorded by Joshua; and, as Moses reckons seven generations from Noah to Joshua exclusive, namely, Abraham, Isaac, Jacob, Levi, Kohath, Amram, and Moses, corresponding to the seven reigns reckoned in the Chinese history between Fo-hee, and Yao inclusive, they contrive to make out the following result.

	Year of the Flood.	Before Christ.
1. *Noah*, called by the Chinese *Fo-hee*, justly offended at the impiety of his rebel offspring, separated himself from them a little before the building of the tower of Babel, and steering his course eastwards, at the head of a select number of adherents, after 200 years peregrination, settled himself and them in one of the northern provinces of China.	235	2114
Here, having settled his colony, and established among them the religion, laws, and government, and imparted to them all the branches of learning, which he had received from his antediluvian ancestors, he died in the 115th year of his reign and 950th of his life, and was succeeded by	350	1999
2. *Shin nong*, alias *Zing-nung*, who greatly improved those arts and sciences left behind by Noah; and, after a reign of 140 years, left the crown to	490	1859
3. *Whang tee*, alias *Hoang tee*, the inventor of the Chinese arithmetic and other arts. He reigned 100 years, and was succeeded by	590	1759
4. *Shau-hau*, alias *Xao-hau*, who reigned 84 years, and left the crown to	674	1675
5. *Chwen hyo*, alias *Chuen-hiou*, who reigned 78 years, and was succeeded by	752	1597
6. *Ti-ko*, alias *Cous*, who reigned 70 years, and was succeeded by . . .	822	1527
7. *Chee*, who, after a reign of eight years, was deposed, and the crown given to his brother	830	1519
8. *Yau*, in the 67th year of whose reign, according to the Hebrew chronology, happened the miraculous solstice, mentioned in the book of Joshua, and in the Chinese annals, though without any year being specified.	897	1452

A more moderate and rational statement is given by Mr Barrow on the subject, of which the following is the substance; that, though the Chinese should be admitted to have been among the first nations after the flood, yet they do not appear to have made such progress in arts and learning, as the Chaldeans, Assyrians, and Egyptians; that it is only from the time of Confucius, (200, or according to others, 550 years before Christ,) that they seem to have advanced in civilization; that, previous to his time, the country was divided into a number of petty kingdoms, under separate chiefs, with a recital of whose reciprocal wars and struggles for superiority, the Chinese annals are chiefly filled; that their historical records are sufficiently abundant and complete, during the last 2000 years, and the transactions of each reign fully detailed without interruption, down to the present time; and that, during this period, the empire of China has been less disturbed by foreign wars or intestine commotions, than any other portion of the world, of which we possess any accounts. Even from this more judicious view of the subject, however, very great deductions must be made; and the authenticity of these sources, from which the Chinese profess to draw their early history, must be considered as more than questionable. Besides a variety of strong presumptions against their credibility, a simple examination of these documents themselves, and of the account of their origin given by the Chinese, is more than sufficient to discredit their whole pretensions to a remote antiquity. Their story is as follows.

Historical records destroyed.

A great diversity of the characters used in writing had begun to prevail in very early times; and the successive Chinese emperors had attempted in vain to reduce them to one uniform and intelligible system. In this, however, they experienced the utmost difficulty, both from the obstinacy of the learned men, who were attached to the different modes of writing, and from the refusal of the chiefs of the different provinces to obey the imperial mandates on the subject. At length the Emperor Shee-hoang-tee, after many bloody wars, having united the supreme authority in his own person, commanded his prime minister, Li-sé, to enter upon the reformation of the written characters. Li-sé, with the assistance of two of the literati, reduced to the number of 10,500 the characters used in medicine, agriculture, and astrology; but found himself utterly unable to introduce the new characters into general use. As the only measure, which could ensure the accomplishment of this object, he advised the emperor to cause all the books to be burned, except those which treated of medicine, agriculture, and divination, and the history of the dynasty of Tsin (from which the emperor himself was descended); and to punish with death all, who should in any respect oppose the execution of this decree, or refuse to employ henceforth the new system of characters. The emperor approved of the plan, and caused it to be put into execution with the utmost severity. The condemned writings, or rather characters, were collected under the heaviest penalties from all quarters of the empire; and about four or five hundred learned men were put to death in the course of this literary persecution. This event took place 213 years before the birth of Christ. About forty years afterwards, the Emperor Ven-tee was desirous to recover the historical documents, especially a work of Confucius called Shoo-king; and an old man was found, who furnished several portions of it from memory. In the reign of Voo-tee, about 150 or 140 years before Christ, some fragments of the ancient books were discovered, which had escaped the general conflagration, and which had been preserved in the ruins of a house, which had been inhabited by some of the descendants of Confucius. One of these was the book Shoo-king, written on tables of bamboo, but greatly destroyed in many places. By putting together, however, the legible portions, and patching them up with the fragments formerly procured from the mouth of the old man Foo-cheng, they restored, as they pretend, 58 chapters of the works which originally consisted of 101; and this has continued to be the sole foundation of the ancient history of China. By the assistance of this document, and a few other imperfect historical memoirs, an author named Se-ma-tsien, produced the first complete history of China, about fifty, or as some say, ninety years before Christ; but he has himself the candour to acknowledge, that he was not able to ascend with certainty more than 800 years before the time in which he wrote; and, according to father Prémare, he is regarded by the greater part of the Chinese authors, as a mere fabler. There was afterwards discovered another work of Confucius, named Tchun-tsioo, which carries the history, however, no farther back than the year 722 before Christ; and, about the year 265 of the Christian era, a small piece upon chronology was found, which begins with the reign of Hoangtee, and ends with the dynasty of Tcheoo, or the year before Christ 782; but it is merely a list of emperors without dates, and with a few notices of events.

Uncertainty and deficiency of early annals.

Such is the account given by the Chinese of the complete destruction, and partial restoration of their most ancient historical records; but it is regarded by many of the most judicious writers on the subject, as altogether a fable, invented at some modern period as an apology for their want of annals to support their pretensions to a remote antiquity; or if true, it affords equally sufficient proof, that no well authenticated ancient document of their history is in existence. Even those ancient records, which they consider as the foundation of their early history, especially the surviving chapters of the Shoo-king, admitting these documents to be both genuine and authentic, are meagre and imperfect beyond what any one will easily be able to conceive, who has heard only of those hyperbolical descriptions of the antiquity and history of China, which have been so long current in Europe. The Shoo-king itself makes mention only of twenty Emperors, and these, too, not in regular succession from one another; but one here and there only, in periods of thousands of years, with frequently no other circumstance, but merely the name. It begins with Yao and Chun, then proceeds to the first dynasty, named Hia, of which only five are named of the 17 emperors, of whom it is said to have consisted. Of the 28 emperors of the second, only five also are noticed; and of the third, down to the reign of Ping-vang, 770 years before Christ, only six are recorded out of fourteen. There is besides in the whole book no epoch mentioned, no dates given, no account even of the duration of the several reigns, except those of five or six princes. Instead of the regular series of astronomical calculations, upon which the ancient Chinese annals are supposed to be founded, and which are understood to have been verified by the calculations of the most eminent modern astronomers, the Shoo-king mentions only two eclipses, and two observations of the solstices, in the space of the first fifteen hundred years of their history; and these also are recorded in such an obscure manner, with so little detail of circumstances, without even the year of the emperor's reign, or the day of the cycle, on which they took place, that modern astronomers have no foundation whatever, upon which to proceed, in fixing the time of these phenomena. It is only from the year 722 before Christ, that their observations begin to multiply; and, from that period to the year 480 before the Christian æra, Confucius has mentioned, with sufficient chronological exactness, 36 eclipses, of which 31 at least have been found completely conformable to astronomical calculation. It has been remarked, as rather a curious circumstance, that this æra of 722 before Christ, at which alone the Chinese chronology commences with any degree of certainty, coincides nearly with the famous æra of Nabonassar, which is placed in the year 747 before Christ, and which forms the basis of the Grecian calculations; and it has been conjectured, that Confucius may have been acquainted with these astronomical observations made at Babylon, when he gave to the Chinese astronomy so sudden, and so great improvements.

The early history of China, besides being derived from such uncertain sources, is so extremely limited, as scarcely to deserve the name. Of the immense collection, known in China by the name of the twenty-one historians, which consists of about 500 volumes, the first 14 volumes comprehend the whole historical memoirs, from the reign of Yao, to the year 200 before Christ; and seven of these 14 contain only genealogical tables. An abridgment of Chinese history of high authority, named Tong-kien-kang mo, as examined by M. De Guignes, presents the following proportions. Of 56 volumes, the half of the second, namely 75 pages, and the whole of the third, namely 111 pages, loaded with notes larger than the text, and consisting chiefly of long moral discourses from the Shoo-king, comprizes the history of the empire, from the reign of Yao to the commencement of the third dynasty, a period of about 1236 years. The history of the third and fourth dynasties, reaching to the year before Christ 207, occupies nine volumes; and the remaining 44 contain the history, from 207 before the Christian æra to the year of Christ 1368.

Such is the general character of the early Chinese history; not as has been pretended, consisting of regular annals, ascending without interruption 3000 years before Christ, written by contemporary authors, full of circumstantial details, and founded upon the most exact astronomical observations; but, on the contrary, extremely limited and ill connected; destitute of events, and full of contradictions; resting upon the most questionable authorities, and often upon mere conjecture; drawn up by authors, who lived far posterior to the times which they describe, and who are frequently divided into the most opposite opinions, and contradictory accounts. We proceed, however, to present our readers with a short sketch of what these historians have recorded; and during the earlier and most doubtful periods, we are happily furnished with a summary of ancient Chinese history by M. de Guignes, drawn from actual inspection of the original materials. That we may occupy as small a space as possible with what is so very uncertain and uninteresting, though necessary to be known as a portion of acknowledged history, we shall merely present a chronological view of each dynasty; and without noticing the progress of every reign, shall content ourselves with selecting the most remarkable events of the period.

First Emperors of China.

	Before Christ.		Before Christ.
Fo-hee	2953	Ti-ko	2436
Shing-nong	2838	Ti-tchee	2366
Hoang-tee	2698	Yao	2357
Shao-hao	2598	Shun	2255
Tchuen-hio	2514		

Before Christ 2953.

Prior to any of these emperors, several chiefs are named in the Chinese annals, who first attempted to civilize the savage natives of the country; but Fo-hee is universally considered as the first, who possessed the title and authority of a sovereign in China. The commencement of his reign is fixed by some of the Chinese historians as high as the year 3300 before Christ; but the whole of his history, and of his successors down to Yao, is entirely fabulous, was written after the birth of Christ, and is disbelieved by the greater part of the Chinese themselves. There is nothing known with certainty with regard to the origin of Yao, or the state of the empire before his time. There are very various calculations, also, respecting the commencement of his reign, which is placed by some in the year 2000, and by others in the year 2411 before Christ. The Shoo-king, as has been already mentioned, never specifies the year of any event; but this was afterwards fixed, according to the calculations and conjectures of the more modern annalists. They are all agreed, however, respecting the existence of Yao; and consider the chapter which relates to his reign, as having been composed in his own time, excepting the first paragraph, which contains his eulogium, and which, with many other passages in the Shoo-king, is acknowledged to be an addition of some future unknown commentator: a circumstance which greatly diminishes the authority of the book, which is the sole foundation of all their ancient history. According to this eulogium, Yao was grave, reserved, discerning, honourable, and every where renowned for the number of his good deeds. By modern authors it is related, that he was the son of the Emperor Ti-ko, a descendant of Hoang-tee; that he was born in the kingdom of Y, but afterwards removed to that of Kee, whence he is frequently named Y-kee; that, at thirteen years of age, he assisted the Emperor Tchee in the government of the empire, by whom he was placed over the country of Tao, and afterwards over that of Tang, whence he is also called Tao-tang-chee; that, at the age of fifteen, he was ten feet in height, and began to reign at sixteen; that he established his court at Ping-vang in Shansee, and ruled by the element of fire,—which is supposed to signify, that he was under the protection of the planet Mars. According to the Shoo-king, he commissioned Hi and Ho, and other astronomers, to observe the revolutions of the heavens, and to proclaim to the people the periods of the different seasons; and that, in the second year of his reign, by the assistance of these learned men, he also fixed the length of the year at 365¼ days, and 366 in every fourth year; which supposes the Chinese to have possessed a correct calendar, long before the Egyptians and Chaldeans. In the twelfth year of his reign, he visited every part of his dominions, and continued to do so once in twelve years, as long as he lived. In the 70th year of his reign, he was desirous to resign the supreme power in favour of the person who should be most capable of governing; but being satisfied neither with his own sons, nor with any of his nobles, he commanded inquiry to be made among his private subjects. A person of the name of Shun was brought before him, of whom the following history is given, which seems to have no other foundation than a wish in the author of it to recommend the virtue of filial piety. Shun was born in the year 2327, and was very much distinguished by his filial obedience. His father had another son, named Siang, by a second marriage, who was a greater favourite than himself, and who repeatedly attempted to take away his life; but, notwithstanding every provocation, he faithfully discharged the duty which he owed to his parents. At the age of twenty years, he became so renowned by his virtues, that, wherever he fixed his residence, multitudes of people settled around him; and at one place particularly, on the borders of the lake Looi-tse, he attracted such numbers, that in two years it became a town, and in the third year a city. As proofs of his filial duty, it is said, that his father, having caused him to build a granary, immediately set it on fire; and, in like manner, having ordered him to dig a well, instantly filled it up; but that Shun, nevertheless, continued to pursue the work without murmuring. It is farther related, that the emperor, having offered him his two daughters in marriage, on account of his great virtues, his father refused to give his consent, and even used means to put him to death; but that still he never permitted himself to harbour any thoughts of revenge. When he was presented to the emperor as worthy to be his successor, it was given as his recommendation, that his father was a man of a shal-

B. C. 2357.

low understanding, his step-mother a cheat, and his brother puffed up with pride; but that, nevertheless, by his obedience, he had succeeded in reforming them all. He was accepted by Yao as his successor, and received his two daughters in marriage. As soon as he entered upon his office, he employed in the service of the state eight sons of a former emperor, Tchuen-hio, who re-established order in every part of the country; and commissioned the eight sons of the Emperor Ty ko to publish the five precepts, namely, the duties of a father, of a mother, of elder sons, of younger sons, and of children. He went in person to the foot of the high mountains, without being alarmed by the fury of the winds, and thunder and rain; and under the protection of heaven and earth, and all the divinities, superior and inferior, examined every thing, and was afraid of nothing. Many troubles and calamities had prevailed during the reign of Yao, in spite of all his exertions. Inundations deluged the greater part of the country; and the remainder was almost entirely covered with forests and wild plants. Animals of every species multiplied so rapidly, that the inhabitants were afraid to show themselves. Yao was in great affliction on account of these evils, but Shun undertook to effect their removal. He appointed Yu to take charge of all that related to fire, who accordingly set fire to the forests, which covered the mountains and plains, and thus obliged the animals to go in quest of other retreats; distinguished the course of the nine rivers, and thus procured provisions; and was so incessantly employed during the eight years which he occupied in this labour, that he three times passed by his own house without stopping to enter. Keoo-tsee taught the people to sow, to plant, and to cultivate the fine fruits; but still they were in want of instruction, and Sie was commissioned to teach them the distinctions which were to be observed among them,—the duties of a father to a son, of a subject to a prince, of a wife to a husband, of a young man to an old, and of friends or equals to each other. In the 73d year of his reign, Yao, having carefully observed the conduct of Shun, proposed to declare him his successor; and though the latter at first declined the proposal, upon the ground of his not being sufficiently worthy, he was constrained to consent, and was invested with the royal authority on the first day of the first moon, in the temple of Ven-tsoo. In the year following he made the tour of his empire; arranged the seasons, months, and days; regulated music, measures, and weights; defined the five ceremonies, the vessels and instruments necessary to be employed. He made this circuit of his dominions every five years; and, during the intervening four years, the nobles came to him annually, when their conduct was examined, and rewards bestowed, or punishments inflicted, according to their merits. In the 80th year of Yao, Yu announced the termination of his labours, in drawing off the waters. He had traced and distinguished all the great mountains and rivers; cut down or burnt up the forests; and appointed the tribute which each province should pay. Here the Shoo-king gives a list of the provinces, the only instance of their being named in the ancient history of China, prior to the year before Christ 722; but a slight inspection is sufficient to satisfy any reflecting person, that the account is utterly incredible, and incompatible with the other circumstances related of the state of the empire; that it could not have been drained and cleared to so great an extent in the time mentioned, and under the direction of one individual; that many of the articles appointed to be paid as tribute, could not possibly have been produced in a country newly extricated from a marshy state; and that many of the provinces, said to have been civilized and rendered tributary, were still, according to succeeding histories, in a state of barbarism, and not even considered as subject to China, long after the year 722 before Christ. The empire, according to the Shoo-king, was at this time divided into nine districts, called Tcheoo, and afterwards into five, called Foo; of which the following account is given: Tien foo, in which was the imperial court, and which was in the centre of the other divisions, consisted of 500 lee;[*] at the distance of 100 lee, the rice was brought in with its stalk; at the distance of 200 lee, without the stalk; at the distance of 300 lee, with its husk; at the distance of 400 lee, not cleaned; and at the distance of 500 lee, cleaned. Heoo-foo consisted of 500 lee, of which the first 100 were set apart as the land of the officers of state; 200 for the magistrates, called Nan; and 300 for the greater chieftains. Sooi-foo consisted of 500 lee, of which 300 were set apart to defray the expence of teaching the sciences; and 200 for the defence of the country. Yao-foo consisted of 500 lee, of which 300 were occupied by the barbarians, and 200 by criminals. Koang-foo consisted of 500 lee, of which 300 were set apart for the barbarians named Man, and 200 for banished persons. According to succeeding historians, these divisions were disposed in a concentric form; that is to say, Tien-foo was in the centre, and the other Foo lay around it, like squares placed one within another; a division resembling that which Ezekiel made in vision of the promised land, from which the Chinese writers are supposed to have borrowed their scheme, and, of consequence, to have produced it at a period posterior to the time of that prophet. But, notwithstanding that Yu had divided the empire into nine provinces, it is recorded, that Shun, in the year following, made a new division into twelve; and though we read, that Yu had completed all that related to the waters, it is said that Shun was employed in directing canals to be dug. Mention is made, in this part of the history, of the persons who were the founders of the three first Chinese dynasties, and who are likewise all made to be descended from Hoang-tee. Yu, the head of the dynasty of Hia, was rewarded by Yao with the title of Pe, with the office of Se-kong, or superintendant of the works, with the family name of Se, and with the principality of Hia. Sie, the ancestor of the princes of the dynasty of Shang, obtained a high office, and the principality of Shang; and it is said concerning him, that his mother, when going in company with some other women to bathe, found an egg, which she swallowed, and in consequence became pregnant of Sie. Kee, the head of the Tcheoo dynasty, obtained the principality of Pin; was exposed at his birth, which his name implies; became afterwards fond of husbandry, in which he made great improvements; was placed by Yao at the head of the department of agriculture, with the title of Heoo-tsee; and was worshipped, in future times, as the deity of the husbandmen.

Early division of the empire.

The whole of this history of Yao's reign is a feeble compilation of trifling and contradictory facts, of events which took place at later periods, or which have been drawn from the history of other nations. If the inhabitants of China were, as here represented, in such a state at this period, as to require to be taught the simplest arts and first duties of life; how is it conceivable, that they had been able, many years before, to make astronomical observations, and to attain so correct a knowledge of the length of the year?

---

[*] Ten lee are one league French.

Yao died in the 102d year of his reign; and the people mourned his loss three years. He is said to have left ten children, none of whom succeeded him; but one of them, named Tcheoo, was afterwards made Prince of Tang, by Yu. Shun, who had assisted Yao in the government 28 years, retired after the death of that prince to the south of the empire, where all the nobles, abandoning Tchoo the son of Yao, on account of his vices, followed to pay him homage, and to proclaim him their sovereign.

Shun, who is equally renowned in China as his predecessor, repaired, on the first day of the first moon after the death of Yao, to the hall of ancestors, gave audience to his grandees, and inquired into the state of affairs. He consulted the twelve Moo, or shepherds, and spoke to them, according to the *Shoo-king*, to this effect. "Every thing depends upon seizing the proper season for procuring the necessaries of life. Treat with kindness those who come from a distance; instruct those, who live in your vicinity; esteem and recommend those, who possess talents; place confidence only in men of worth; do not frequent the company of those, whose morals are corrupted: In this way you will succeed in reducing to obedience the barbarians of Man and of Y." He then addressed himself to his nobles, and demanded, if any among them was capable of governing, that he might place him at the head of his ministers. They unanimously presented to him Yu, who was the superintendant of the public works; and he was immediately declared prime minister, with the management of every thing relating to the land and the waters. Kee was commissioned to cause all kinds of grain to be sown in their season, in order to relieve the wants of the people; and Sie was invested with the office of instructing them in their duties, in order to preserve peace and concord. He then spoke to Kao-yao, and said, "Strangers excite disturbances. Sie, there are among the people of Hia robbers, assassins, and persons of corrupted morals; I appoint you judge, that you may administer the five rules for punishing crimes with proportionate penalties. There are three places for putting those into execution. There are districts for five degrees of banishment, and there are in these districts three kinds of dwellings."* He entrusted Tchooee with the care of the public works; and gave to Y the superintendance of the mountains, forests, lakes, ponds, plants, trees, birds, and animals; though these two departments would seem to have been included in that of Yu, who had the management of all that related to the land and the waters. Pe-y was appointed to watch over the three ceremonies, and received the office of Tchi-tsong, with these words: "From morning to evening be full of fear and reverence, and continually upon your guard to have your heart upright and free from passion." Kue-ee was appointed Master-musician, with this exhortation: "Instruct the children of the princes and nobles, so that they may be sincere, affable, complaisant, grave, and firm, without being stern or cruel. Form their understanding, that they be not proud. Explain to them your sentiments in verses, and songs, in which the words accord with the notes. If the eight tones accord, and if there be no confusion, the gods and men will be united." Then, addressing himself to Long, he said, "I detest those, whose tongue sows division, and throws every thing into disorder. I give you the office of Na-yan, that you may report to me with fidelity and sincerity all that is spoken." After which, addressing them all, he exhorted them to fulfil their respective duties. Besides these and other discourses, found in the Shoo-king, and which have every appearance of having been afterwards composed, and put into the mouths of those antient personages, with a view to convey and impress moral instruction, there are several conversations recorded as having taken place between the emperor and his ministers, of which the following may be given as a specimen. "When the great inundation," said Yu, addressing the Emperor, "rose even to the heavens, encompassed the mountains, and covered all the high places, the people were troubled, and perished in the waters; then I employed the four Tsay," (kinds of carriages,) "traversed the mountains, and cut down the woods. Along with Y I collected provisions of grain and the flesh of animals, for the subsistence of the people; and formed channels for the rivers, which I caused to flow towards the four seas. Assisted by Tsee, I caused the fields to be sown, and, by uniting the flesh of animals with that of fishes, the necessaries of life were provided. Provisions were conveyed to the places where they were wanted, and exchanges of articles were made. I then distributed the departments, and gave to them a form of government." Kao-yao bestowed great praise upon such conduct, and Yu continued, "Prince, be attentive; decide upon the object which you ought to have in view; examine the occasions on which it is necessary to deliberate, or to act; and consider how you may render the deliberation or the execution invariable. If your ministers are faithful and in concord with one another, they will attend to your decisions, and you will clearly receive the commandments of Chang-tee, who will load you with his bounties." To this discourse the emperor replied, "A minister touches (or approaches) me very near, and he who touches me very near is a minister. He is to me as a foot, a hand, an eye, an ear. He assists me to govern the people, and extends my benefits to every place." "When I wish to hear the six Lu, the five sounds, the eight tones, I examine my conduct; I wish that songs should be performed to me, accompanied by five tones. When I commit faults, I ought to be told of them; and it is highly blameable to praise me to my face, in order to censure me in my absence. When a thoughtless man utters pernicious words, let him be strictly questioned, in order to verify what he has spoken; let him afterwards be punished, and a register kept of the penalty inflicted. If he promises to amend, set his words to music, and let them be sung to him every day. If he reforms, give notice of it to the emperor; if not, punish the guilty." "How just are these words!" replied Yu. "The reputation and glory of the emperor have reached to the shores of the sea, and to the ends of the world. The wise of all countries desire to enter into his service. He knows how to reward merit. He examines all things. I have not been like Tan-tchoo, the son of Yao, vain, proud, adventurous, dissipated, cruel, and restless. In the places, where there was no water, he wished to travel by sailing; at home, he was surrounded with licentious persons, and so he succeeded not to the throne of his father. To avoid such errors, I married the daughter of the Prince of Too-shan. I remained with her four days. Afterwards, though I heard the cries of my son, I thought only of the labour, which

---

* Those who consider this part of the Shoo-king as having been composed in the time of Shun, find great difficulty in explaining the words "people of Hia," as that dynasty was not then in existence, and as the Chinese were never known by that name.

History.
B. C. 2200.

I had undertaken to draw off the waters. I divided the empire into five departments, and I extended my progress as far as 5000 lee. Every province had 12 chiefs. I confined the four seas within their limits. The Miao alone could not be subdued." "It is you," replied the emperor, "who have induced my people to perform the good to which I exhorted them. Kao-yao has given great renown to your work, by establishing the five punishments; and is penetrated with esteem for your worth." Such is an example of those numerous imperial conversations and moral reflections, with which the ancient history of the Chinese abounds; and which often form the whole annals of many a reign. Their sameness, also, is so great, that it will be very unnecessary to fill our pages with frequent extracts; and the few events, which occur through the course of whole dynasties, may be compressed within a small space.

Shun, we are told, erected eminences on the twelve mountains of the twelve provinces as places of sacrifice, regulated the different kinds of music, and attended at the performance of songs and dances. One author ascribes to him the invention of a lyre with five strings, upon which Kue-ee, his chief musician, performed various airs, as a reward to the grandees, and as a mean of exciting them to a virtuous conduct. In the 32d year of his reign, it became necessary to levy troops; and a long discourse upon the subject took place between Shun, Yu, and Kao-yao, which concludes with the exaltation of Yu to be prime-minister, as Shun had been under Yao. A long history is given, by a later historian, of a law revealed from heaven to Yu, consisting of nine articles, which were represented on the back of a tortoise that came out of the river Lo. This table of numbers, called Lo-shoo, is supposed to have been borrowed from the doctrine of Pythagoras, and is considered by the Chinese as the source of all human knowledge. According to it, Yu divided the empire into nine provinces, nine mountains, nine rivers, and nine lakes, by which numbers many mysteries are understood to be expressed. In the 35th year of his reign, Shun commanded Yu to march against the Miao; but nothing is related of the effects of this armament, except that, after its return from the field, the Miao made a voluntary submission. Shun died in the year 2208 before Christ, while he was visiting the southern provinces; and the people mourned three years.

Yu, in order to avoid the sons of Shun, retired to Yang-tching, where the nobles followed and put themselves under his sway, in the year before Christ 2205. With the reign of this prince begins

Shao-kang	2097	Tee-kao	1848
Tee-shoo	2057	Tee-fa	1837
Tee-hoaee	2040	Kie, or Kooei	1818

This dynasty lasted 440 years, according to some authors, and 480 according to others; and may be considered as a period of mere conjecture.

Yu is represented by the Chinese genealogists as also a descendant of Hoang-tee, but the Shoo-king makes no farther mention of him after he began to reign; and the little that is related concerning him, has been collected or conceived by later writers. Having ascended the throne, he assembled the nobles upon mount Too-shan, in the province of Kiang-nan, and explained to them the principles, by which he intended to govern. He placed in a particular situation a tambour, two different kinds of bells, and another instrument, of which the name is not known; and each of his chief officers, when they came to demand an audience, were appointed to strike upon one or other of those instruments, according to the subject of his application. According to the usage of his predecessors, he chose one of his ministers, named Y, as his successor, and having inquired into the conduct of his officers of state, set out to visit his dominions. Having met a criminal in his progress, he descended from his chariot, and burst into tears, saying, "If there are men in the empire, who do not obey the laws, the blame falls upon me. It was not thus in the time of Yao and Shun; but all the people then had only one heart." Some years after, he went into the provinces in the south, and put to death a chief of the name of Fang-fong-shee, because he was the last who appeared at the great assembly, which he had summoned; and he died after a reign of eight years.

Y, who had been nominated his successor, left the empire to Tee-kee, the son of Yu, by whom, after his death, he was honoured with animal sacrifices. This prince assembled the six generals of his army, and gave them to march against a rebel chief, who despised the laws of the empire; and some authors ascribe to him the first opening of mines and preparation of metals.

Tay-kang, according to the Shooking, was like a statue upon the throne, entirely the slave of his passions, and utterly regardless of the wishes of his people, by whom he was held in the greatest detestation; but the paintings, palaces, and extreme luxury, with the love of which this prince is reproached, are not very compatible with the recent instruction of his subjects in the art of husbandry, and in the first principles of social life.

During the reign of his brother Tchong-kang, by whom he was succeeded, took place one of the two eclipses mentioned in the Shoo-king, and fixed by succeeding annalists in the year before Christ 2159. No more of the princes of Hia are mentioned in the Shoo-king, and the remaining history of this dynasty is a miserable patch-work by later writers. Siang, the son and successor of Tchong-kang, was slain by the rebel Han-tsoo; but the widow of the dethroned prince, being left pregnant, brought forth a son named Shao-kang, who soon became distinguished by his virtues, collected the ancient subjects of his father, attacked and slew the usurper, and was reinstated on the throne of his ancestors.

In the reign of Kong-kia, it is said, that iron was taken from a mountain and formed into swords. During the same period flourished a remarkable person named Lieoo-lee, who knew how to tame serpents, and to make them obey his voice. An idle story is related of one of his serpents having died, and been given to Kong-kia to eat, who was so delighted with this new species of food, that he wished for more, to the great alarm of Lieoo-lee, who retired with his tame stock to a distant place. Kong-kia is reproached with having observed the worship of genii, and given himself up to every kind of vicious excess; and his subjects, imitating his example, the whole empire was thrown into a state of the greatest disorder and weakness.

Eating of serpents.

Kie, another wicked prince, governed the people by

means of a minister named Tchao-leang, who gave his sovereign the most wicked counsels. His wife Moey-kee also ruled him at her pleasure, and led him into numberless extravagances. He built magnificent palaces, the apartments of which were adorned with ivory and precious stones, in which he shut himself up, regardless of his duties as a sovereign, and abandoned himself to the grossest debaucheries. A prince of the name of Tching-tang, who ventured to remonstrate with him upon his unworthy conduct, was cast into prison; but being afterwards liberated, and joined by Tchong-koo, one of the ministers of Kie, they attacked this Chinese Sardanapalus, in his royal brothel, which he named "the palace of the night," and, having driven him from the throne, established

Of this dynasty, the Shoo-king contains only three or four events; and the duration of the respective reigns have been conjectured by writers, posterior even to Sema tsien, who lived about a century before the birth of Christ. Its whole history is full of uncertainty, and its continuance is fixed by one historian, at 496; by another, at 600; and, by a third, at 645 years. The Shoo-king gives the same account of Tching-tang, as of the other founders of the Chinese dynasties, namely, that he persuaded his soldiers to assist him in dethroning the reigning family, by pretending to have authority from heaven to take arms. After his victory, however, he became very apprehensive, that posterity would condemn his conduct; but one of his ministers named Tchong-hoey, in a long address, which is all that the Shoo-king records of his history, succeeded in dispelling his fears. It is related of him, by other historians, that he fixed the beginning of the year at the 12th moon, which falls in winter; that he made use of chariots drawn by white horses with black heads; that he sacrificed white oxen, and formed the calendar called Kea-yu; that he afterwards visited his eastern frontiers, and charged his great men to govern the people faithfully; and that he bestowed certain districts upon the descendants of Yu, and other virtuous characters. During a season of scarcity, he shaved his head, cut his nails, and went to a high place, where he addressed his prayer to heaven in these words: "Is it because the empire is not well governed, or because my palaces are too magnificent, or because my women are too much addicted to luxury, or because I am too much inclined to listen to flatterers, that no rain is allowed to fall?" Immediately after this supplication, the clouds gathered, and rain fell in abundance. Tching-tang upon the occasion composed a piece of music, and caused an inscription to be engraved upon all the vessels of which he made use, to this effect: "Correct yourself, cease not to correct yourself."

History.
B. C. 1500.

In the first year of the reign of Tay-kia, according to the Shoo-king, the minister Ee-in offered a sacrifice to Tching-tang; presented the new king in the temple of his ancestors; pronounced the eulogium of the deceased sovereign, and gave instructions to his successor. He shewed him that, in proportion as the family of Hia followed the dictates of right reason, they were prosperous and happy, but were overwhelmed with calamities as soon as they forsook the path of virtue; that their ruin occasioned the elevation of the family of Shang, and that Tching tang, by the destruction of tyranny, and the exercise of clemency, both established his own authority and gained the love of his people. Tay-kia proving inattentive to these advices, Ee-in, in order to preserve him from the company of viscious persons, caused a palace to be built at Tong, where the tomb of Tching-tang was erected, conveyed the young prince thither, where he improved so much under his care, that at the termination of the third year of mourning, he clothed him in the royal robes, and brought him back to Po, where he addressed him again in public, and received from him, in reply, a full profession of his reformation.

Prodigy.

At the accession of Tay-voo to the throne, a remarkable prodigy is said to have taken place. A mulberry tree, and another of the name of Ko, sprung up in the palace, and grew so rapidly in the course of one day, that a man was not able to grasp them in his arms. Tay-voo, in great alarm, consulted one of his ministers, Ee-tche, who exhorted him to become virtuous; and the prince, having followed his advice, the trees immediately died. The family of Chang recovered its ancient splendour, and distant nations, to the number of sixteen, sent embassies to Tayboo, in testimony of their esteem. As a reward for his virtue, says the Shoo-king, he reigned 75 years.

Poen-keng, upon ascending the throne, proposed to remove his court to Yn; but he experienced great opposition from the people, who refused to follow him. Upon this occasion, the Shoo-king relates, that he assembled the most mutinous, reasoned them into obedience, and instructed his subjects in general in their respective duties. The whole story is worthy of notice in this view, that it furnishes a proof, from the Chinese annals themselves, that their empire, supposing it to have existed at this distant period, was of very limited extent, and more like an ambulatory tribe under their chief, than a powerful or numerous people, provided with magnificent palaces and well built cities.

Voo-ting, named also Kao-tsong, mourned for his father three years, and preserved a profound silence during all that time, leaving the care of the government to Kan-pan. But, as he persisted in his retreat and taciturnity, his nobles represented to him that a king ought to issue his orders, and apply himself to the business of the state. The prince replied in a written communication, that he kept silence from a dread of being unable to imitate the virtue of his predecessors; but that, while he was meditating upon the law, the Tee had shewn him in a dream a minister who would speak for him. A painting of this person, says the Shoo king, was made by the direction of Voo-ting, and a general search was made for the reality. After much enquiry, a person named

Yue, who followed the occupation of a mason, was found in the country of Foo-yeen in Shansee, who bore an exact resemblance to the portrait; and, having been brought to Voo-ting, was appointed his prime minister. A long discourse took place between them, in which many useful maxims and moral exhortations are expressed; but which are only a repetition of what are recorded almost in every reign.

Under the reign of Tee ee, Kee-lee, a prince of the family of Tcheoo, was appointed to the command of the army, and successively defeated the barbarians of Yen-king, of Yu-voo, and of Y-too. He received in reward of his services, a kuey or musical stone, a vessel full of wine, and the title of Keoo-pe, or prince of the empire. He was succeeded in his principality and honours by his son Tchang, or Ven-vang, who is one of the most distinguished personages among the Chinese worthies. His mother, Tai-gin, experienced no inconvenience during her pregnancy, and brought him into the world without pain. At his birth, it was predicted that he would be a great man; and his grandfather Tan foo said, at the first sight of him, "this child shall perpetuate my race." He imitated the virtues of his ancestors, respected the wise and the aged, collected learned men around his person, appointed officers for levying the revenue, put the lakes and bridges into a state of good repair, repressed the power and boldness of the vicious, established order every where, and provided for the support of widows, orphans, and old men. Ven-vang married a virtuous princess, named Tay-su, by whom he had ten children, the youngest of whom named Fa, the same who was afterwards called Voo-vang, gave early indications of greatness, and was appointed by Ven-vang to be his successor. By the command of Tee ee, Ven-vang marched to the western frontiers, and subdued the barbarous people Kuon-ee; and afterwards to the north, where he was equally successful against the Tartars of Kien yun.

Sin, or Sheoo, the son and successor of Tee-ee, was a worthless prince, crafty, vain, profuse, and much addicted to wine and women. He was so strong and courageous, that he was able to subdue the most ferocious animals; and is considered as the inventor of the little ivory sticks, which the Chinese employ in eating their food. He married a princess, named Tan-kee, to whose will he became entirely subservient, and employed himself wholly in music, dancing, and amassing wealth. He kept a multitude of dogs, horses, and wild beasts enclosed in parks; despised the gods, and thought of nothing but his pleasures. He filled a pond with wine, collected delicacies of every description, and assembled around him the most licentious persons of both sexes. He contrived a new mode of punishment, according to which the sufferer was compelled to walk upon a large bar of red hot iron, which was so placed, that upon falling from it he was received into a fire of live coals, an exhibition which occasioned much merriment to Tan-kee. Ven-vang, Kieoo-hieoo, and Oo-heoo, were at this time the three principal men of the empire. The second had a daughter whom he gave to Sin; but upon her refusing to take part in his debaucheries, he caused her to be cut in pieces, and presented as food to her father. Oo-heoo having remonstrated with the emperor upon such barbarity, he was put to a similar death. Ven-vang lamented these events in silence, of which the king being informed, threw him into prison, lest he should cause an insurrection among the people, who began to be extremely discontented. Ven-vang, during his confinement, applied himself to the study of Y-king, a work ascribed to Fo-hee, and which shall afterwards be described. The people of his principality, however, who regarded him as their parent, continuing to petition for his liberty, and the neighbouring barbarians beginning to make incursions into the empire, Sin at length brought him out of prison, and put him at the head of the army. Ven-vang prevailed upon the emperor, by presenting him with the country called Lo, to abolish the punishment of the iron pillar; and was declared, in return for his services, chief of all the western vassals. But Sin was surrounded by wicked ministers, who attempted to calumniate the conduct of Ven-vang, and to accomplish his destruction. Their machinations excited the great vassals of the empire to revolt in support of Ven-vang; but, instead of putting himself at their head, he persuaded them to return to their duty. The virtues of Ven vang rendered his name so celebrated, that neighbouring princes applied to him as umpire in their contentions; and it is related, that, when those of Yu and of Tooy, were on their way to his residence for this purpose, they were so impressed with the flourishing and orderly state of his territories, that they were ashamed of their own folly, voluntarily abandoned their disputes, and returned to imitate this excellent prince. Forty kingdoms are said to have submitted voluntarily to the sway of Ven-vang; but, in the Chinese annals, even long posterior to this era, a village was called a kingdom. In proof of his good government, and of the superior civilization of his subjects, it is related, that, in his dominions, the lands were carefully divided, and each family provided with a sufficient quantity of ground for their support; that the habitations were surrounded with mulberry trees, and the women employed in rearing silk worms; that there were in every house five hens and two swine, to supply proper food for the old men; that the people had been instructed to plant trees, and rear domestic animals; that the peasants were seen every where peaceably employed in their labours, and the travellers pursuing their journey in safety. But, if all these marks of improvement were now seen for the first time in Shensee, which had been first inhabited, and were peculiar to the principality of Ven-vang; what becomes of the great empire of China, which, according to its historians, had already subsisted 1800 years in a state of grandeur and civilization? But, to return to Ven-vang, who, after all those great actions, is called by one of the historians who celebrate his praise, a barbarian of the West, he continued to subdue the savage people of Mee-sin, of Kee, of Yu, and of Tsong, all dwelling within the limits of the province of Shen-see, and died soon after in the 96th year of his age. He was succeeded by his son Fa or Voo-vang, who immediately reviewed his troops and set out to subjugate the country of Lee towards the east. Sin, in the mean time, continued to despise all the advisers of his friends, and to punish every one, who ventured to remonstrate with him upon his conduct. To one of these unhappy persons he said, upon sentencing him to death, that he had heard, that wise men had seven holes in their heart, and that he would take out his to ascertain the point. This was his last act of cruelty. Voo-vang, at the head of 800 vassal chiefs, marched against the monster, deprived him of the empire, and founded

The history and chronology of this dynasty are not less involved in uncertainty, than those of the two preceding. The Shoo-king affords no data for fixing the period of its commencement; and even the historian Se-ma-tsien does not venture to assign any dates, till the year 841 before Christ. The whole account of the expedition of Voo-vang, according to the Shoo-king, exclusive of his harangues to his followers, is comprised in this, that as soon as he had begun the attack upon the army of Sin, the royal forces fled in such terror that they destroyed one another; that he restored the empire of Chang to its former state, set at liberty those whom the emperor had imprisoned, distributed among the people the wealth which the tyrant had amassed in his tower of Loo-tay, returned to his own court at Fong in Shansee, and disbanded the whole of his army. Other historians have added, or rather invented, the following particulars: That the army of Sin consisted of 700,000 men, who dispersed upon the first appearance of Voo-vang; that Sin then shut himself up in his tower of Loo-tay, to which he set fire, and perished in the midst of his treasures; that Voo-vang put to death the cruel queen Tan-kee, and entered the imperial residence, at the head of his generals, amidst the acclamations of the people whom he had delivered. Voo-vang restored the kingdom of Shang to Voo-keng; but, according to others, he bestowed it upon his own brother Kang-sho, to whom he addressed a long discourse on morals and government, which is recorded at length in the Shoo-king. He divided his dominions into numerous principalities, which he conferred upon the most distinguished chiefs, who are all made out to have been the descendants of Hoang-tee, of Yao, of Shun, of Yu, of the races of Hia and Shang. Having offered sacrifices to his ancestors, and appointed various political regulations, he gave his attention entirely to the study of philosophy, and placed himself under the tuition of Kee-tse, elder brother of the late Emperor Sin, with whose instructions, entitled, "The Sublime Rule," a whole chapter of the Shoo-king is filled. As a reward for his services, this philosopher received the kingdom of Corea, which he is said to have brought from the rudest barbarism into a state of the highest civilization, though the same people are described, ages afterwards, as still in a savage condition.

B. C. 1000.

As Tching-vang, the son of Voo-vang, was only thirteen years of age at the death of his father, his uncle Tcheoo-kong took charge of the government of the empire, and the education of the young prince. The worthy regent, however, having been charged by his enemies with entertaining designs against the life of the young king, thought it prudent to withdraw from court; and, by the machinations of the same persons, who were also uncles of the prince, Voo-keng, son of Sin, who had been allowed by Voo-vang to rule over the country of Yn, was excited to take advantage of the youth of Tching-vang, and to raise the standard of rebellion. The innocence of Tcheoo-keng, however, having been miraculously proved, he resumed his functions, and, together with Tching-vang, subdued Voo-keng, and various neighbouring tribes. The history of the first eleven years of this reign, abounds in political measures and geographical descriptions, which are utterly irreconcileable and unintelligible. The young prince is represented, at one time, as addressing sage discourses to his assembled grandees; and, at another, as receiving instructions from his guardian Tcheoo-kong. The Kia, the Shang, or the Yn, are repeatedly spoken of, not as the descendants of the dethroned dynasties, but as distinct nations, occasionally rebelling, not against the reigning family, as might be supposed from the history, but against the nation of the Tcheoo. Tching-vang is related to have found it necessary, for the peace of his dominions, to remove his imperial residence to a new city, which he built on the banks of the river Lo in five days; and immediately to have left this new habitation under the government of Tcheoo-kong, and returned to his former abode at Fong in Shen-see. From the eleventh to the thirty-seventh year of the reign of Tching-vang, nothing is recorded concerning him, except that, feeling his end approaching, he called for water to wash his face and hands, put on his royal vestments, assembled his nobles, and recommended to them his son Tchao-kong as his successor; of whose coronation a long and minute description is given by the Chinese annalists. This prince is known in history by the name of Kang-vang, *i. e.* "peaceful prince;" but nothing is recorded concerning him till the 12th year of his reign, when he is described as recommending the country of Lo to the care of his prime minister, while he should be absent at Fong. In the course of this address, he speaks of the small number of his people the Tcheoo; and of the care, which was necessary to preserve their authority over the people of Yn, who, of consequence, could not be much more numerous; and who, when both united under one chief, could not form that vast and powerful empire which China is represented and supposed to have been during ages. Prior to this date, nothing more is said of Kang-vang, but that he honoured the gods, and preserved peace in his dominions; that the prisons were empty, and that for forty years no punishments had been inflicted; that, in a word, the times of Yao and Shun were restored during his reign. Of the two succeeding emperors, Tchao-vang and Moo-vang, nothing is recorded in the Shoo-king, except a discourse by the latter addressed to one of his viceroys, and an official sketch of the criminal code of the empire. But other historians relate of Moo-vang, that, in the 17th year of his reign, he made war upon the barbarous people named Joug, and afterwards went to visit a princess, called "the Mother of the King of the West." On the western frontiers, also, of his empire lived a very extraordinary man, who possessed the secret of transforming himself

Chinese magician.

into different shapes, of separating mountains, and of transporting cities from one place to another. With this person the king resided ten years, without troubling himself about his kingdom; and, during that time, was entertained by the magician with admirable music, and conveyed from place to place in enchanted chariots. While he was amusing himself in this manner, his subjects became discontented, and rose in rebellion; but Moo-vang, returning promptly to his court, subdued the insurgents, and afterwards marched against the barbarians of Kuen-jong, whose country is described as situated at the extremity of the empire, but, nevertheless, as not far from the capital in the province of Shen-see.

In the eighth year of the reign of Y-vang, mention is made of a chief named Hiong-kiu, prince of the barbarians of Tsoo, who subdued the other barbarians in his neighbourhood, and made his sons rulers over all the nations to the north of Kiang; and, as this chief denied that he was a Chinese, though numbered by historians among the descendants of Hoang-tee, it follows, from the account of his conquests, that neither Hoo-quang, nor Kiang-nan, nor any of the provinces farther south, were at this time, (888 years before Christ,) or had ever been, under the dominion of the Chinese, which reduces its extent more than one-half of what it is described to have been in the earliest ages.

In the 30th year of the reign of Lee-vang, whose name signifies "cruel prince," it is recorded that there happened a great drought; that the barbarians of Tsoo made inroads upon the empire on the south, the Tartars on the north, and the people of Hoay on the east; that the prince of Kuo, who was sent against them, returned with little success; and that all these calamities, united with the cruelty of the emperor, rendered the people extremely discontented. The barbarians of Jong advanced into Shen-see, and were joined by the disaffected chiefs in such numbers, that Lee-vang was obliged to seek safety by flight; and, (which proves that his dominions were not very extensive,) had only to cross the river Hoang-ho, to be out of his kingdom, and to find himself secure in Shan-see. It was chiefly in this reign, that the independence of some vassal princes, especially those of Tsin, of Tsee, and Oey, was established; and that a kind of confederation was formed among them, at the head of which, as both sovereign and pontiff, was the prince of Sigan-foo in Shan-see. Many other princes begin to be mentioned at this period of the history, whose states were comprised chiefly in the provinces of Shen-see, Shan-see, Pe-tche-lee, Honan, and Shang-tong. All these principalities, which afterwards formed the Chinese empire, were of very small extent; and several of them comprehended only the territory of a city of the first order, situated in the midst of the native barbarians.

Chinese history assumes a more authentic appearance.

It is in the reign of Siuen-vang, that Se-ma-tsien, the first historian of China, and who lived about a century before Christ, begins to affix dates to his narrative; and from this period, therefore, the Chinese history begins to have at least the semblance of greater certainty. It is recorded of this prince, that he resolved to take the number of his subjects, in opposition to the advice of his ministers, who represented to him, but without effect, that the officer, who presided over that department, knew the number of families, of births, and of deaths; but that, by openly making a survey of the people, the more powerful vassals might become acquainted with the state of the empire, and encouraged to excite commotions.

During the reign of Yeoo-vang, an account of the empire is given, as it existed in the year before Christ 774, which proves, that it was still comprehended in the provinces of Shen-see, Shan-see, Pe-tche-lee, Honan, and Shang-tong, great part of which was occupied by barbarians; that it was surrounded by the barbarians of Jong and King on the south; by the states of Oey, Yen, and the barbarians of Tie and Sien-yu on the north; by the states of Yu, Kuo, Tsin, Ho, Yang, Goey, and Shooy on the east; by those of Tsee, Loo, Tsao, Song, Tong, Sie, Tseoo, and Kiu on the east. These different states, which were held by the descendants or allies of the reigning dynasty, were so limited and unsettled, that it was no uncommon event for a prince and the whole of his subjects to transport themselves from one territory to another. Yeoo-vang, by his foolish conduct, increased the troubles and dangers to which the empire was exposed. Perceiving that Pao-se, a young woman, to whom he had completely attached himself, was not much disposed to laugh, he used all the means in his power to excite her risible faculties, but without effect, till he thought of causing fires to be kindled, and drums to be sounded, as if an enemy had appeared; and as the vassal princes, who hastened to his assistance, expressed their astonishment, Pao-se laughed excessively at their disappointment, which pleased the emperor so much, that he repeated the same trick so often, that at length, when he was in reality attacked by the prince of Shin, his signals were disregarded by his chiefs, he himself was slain, and Pao-se, with all his treasures, fell into the hands of the enemy. This trifling story of an imperial hoax is deserving of notice, only as an additional proof of the limited extent of the Chinese empire, when the lighting of fires and beating of drums was sufficient to collect the surrounding vassals.

Fatal hoax by a Chinese prince.

During the reign of Ping-vang, also, mention is made of a prince of Tsin, who was admitted into the number of the chief vassals, upon the ground of his keeping the barbarous tribes in awe; but who is himself described, in some of the Chinese books, as a complete barbarian, whose subjects were still utterly savage in their manners, though they had resided more than 100 years in the province of Shen-see, in the heart of which the Chinese emperors had ruled by this time nearly 400 years. A circumstance, which sufficiently demonstrates, that, even according to the accounts of the Chinese historians, sciences, morals, and good government, had not made so great progress in China in ancient times, as they themselves pretend. Towards the end of the reign of Ping-vang, the princes of Loo began to exercise certain privileges, which belonged to the emperor alone; and the history of this period is filled chiefly with details of the contests which the different vassal princes carried on with one another. It is from the end of this reign, about the year 722 before Christ, that Confucius commenced his history, called Tchun-tsieoo, or History of the Prince of Loo, which was his native country; and that the Chinese annals assume a more authentic appearance. But, from the view, which has been given of the preceding ages, which may be considered as the ancient and fabulous period of Chinese history, it is evident, that of the 15 provinces of the empire, ten were hitherto occupied solely by barbarians; that of the other five, a great portion was still possessed by equally savage tribes; that there were in the midst of these a few towns or villages, with some cultivated spots around them, which were called kingdoms; and that the Chinese nation, instead of having been at this period a numerous, rich, and powerful people, consisted of a few wandering tribes, moving their habitations from place to place, as circumstances required. The remaining history of the dynasty

Commencement of the history by Confucius.

State of the Chinese empire at this period.

of Tcheoo is occupied almost entirely with an account of the wars among the tributary princes; and is called by the Chinese, "the years of war," or "the warlike ages." Several of these vassal chiefs became so powerful by the conquest of their neighbours, that they soon began to disregard the authority of the emperors, who, during a space of 400 years, had more the name than the power of a sovereign. During this turbulent period, many kingdoms arose and disappeared, of which the most powerful towards the conclusion of the dynasty were Tsoo, governed by Kao-lie-vang; Yen, by Hiao-vang; Oey, by Ngang-lee-vang; Tchao, by Hcao-tching-vang; Han, by Huon-hoey; Tsee, by Vang-kin; and Tsin, by Tchao-siang-vang. This last mentioned prince had assumed, in the year before Christ 288, the title of Emperor of the West; and, in 255, dethroned, without a struggle, the Emperor Nan-vang, who had never possessed either dominions or authority. This introduced,

Hiao-ven-vang	250	Eul-shee-hoang-tee	209
Tchoang-siang-vang	249		

The most celebrated prince of this dynasty was Shee-hoang-tee, named also Tching, who subdued the numerous kingdoms which had risen upon the ruins of the imperial dominions, and completely re-established the ancient power of the empire. He greatly extended its boundaries by new conquests, especially in the province of Quang-tong, and the adjoining districts, which had never been subjugated; and transported 500,000 men to occupy and preserve his new territories. He gained possession also of the country of Ortoo, constructed 44 cities along the river Hoang-ho, united the different portions of wall. which had been raised by the princes of Tchao and Yen, against the invading Tartars; and thus completed at length the great wall, after having sent an army of 100,000 men against the Hiong-noo, or Huns, whom he drove to a great distance from his frontiers. In the 34th year of his reign, 213 before Christ, he commanded all the books and writings in the empire to be burned, except those which treated of medicine, divination, and agriculture; a measure, which he conceived to be necessary, in order to abolish the multitude of synonymous characters which had been introduced into the language, and to compel the literati to adopt a more uniform mode of writing (see p. 218.); or, according to others, as a most effectual mean of obliterating the renown of his predecessors, and of securing the first place to his own name in the annals of the empire. In the 32d year of his reign, it is related, that a star fell to the earth, which immediately became a stone; and that some persons caused these words to be engraved upon it: "Shee-hoang-tee is drawing near his end, and his empire shall be divided;" but the emperor immediately commanded the stone to be broken in pieces, and all the inhabitants in the neighbourhood of the place, where it was found, to be put to death. Having, at length, after numerous wars, settled his dominions in a profound peace, his ministers advised him to erect new principalities for the establishment of his younger sons; but he reminded them of the troubles, which had been excited under former dynasties, by the contentions and ambition of the dependent princes; and resolved rather to build palaces in different cities, for the inferior branches of the imperial family, where they should be maintained at the expence of the emperor, according to their rank, without possessing any authority over the people; a regulation which has continued to be observed in China from that period to the present time. Under the reign of his successor, whose cruelty, licentiousness, and impolitic measures had excited a general insurrection throughout the empire, appeared the famous Lieoo-pang, who was successively a private soldier, a captain of a troop of robbers, a general, a petty prince, and, at length, usurper of the throne, and founder of

The most celebrated sovereigns of this dynasty were, Ven-tee, a wise and virtuous prince, who greatly exalted the imperial dignity, and increased the wealth of the empire. He was remarkable at once for his frugality and generosity. He forbade the employment of gold and silver in the utensils of his palace, and the use of silk in the dress of his women; and by his economical style of living, he was able to remit one half of the ordinary taxes, and to maintain all the aged poor in his dominions at his own expence. He was careful to encourage agriculture by his patronage and example. He was also a great lover of learning; and promoted the search after the remnants of the ancient writings, which had been destroyed. He enlarged the boundaries of the empire towards the south; and repulsed the Tartar tribes, who had taken advantage of the troubles preceding his reign, to make incursions into the Chinese territories.

Voo-tee was a prince of excellent qualities, but naturally inclined to war. He yielded, however, to the advice of the wise men whom he consulted, and who all united in preferring a state of peace to the most just and successful military enterprises. He promoted the republication of those books, which had escaped the general ruin, and caused the morals of Confucius to be taught in the schools. His martial spirit having been roused by the inroads of the Tartars, he drove them beyond the great wall with signal success; and is said to have pushed his conquests over to Siam and Bengal. But both these princes, with all their wisdom and talents, were much addicted to the tenets of the Tao-tse, or immortals, who pretended to prepare a liquor, which rendered man exempt from death. The grandees of Voo-tee were grieved with the infatuation of the emperor on this subject, and presented frequent remonstrances without effect. One of them, happening one day to be in the Emperor's presence, when the mysterious beverage was brought to him, suddenly seized the cup and swallowed its contents. The mo-

Practical argument against the superstition of the emperor.

narch, enraged at such presumption, gave instant orders that he should be put to death. "Your command is of no avail," said the courtier, without emotion; "if this liquor hath rendered me immortal, you have no power to deprive me of life; and, if it has left me still subject to death, you rather owe me a recompense for having exposed the imposture." This answer saved the life of the minister, but did not cure the monarch of his credulity.

Exemplary empress.

Ming-tee, famed for his clemency and wisdom, made choice of a lady as his empress, who was a pattern of modesty and discretion, and who never made use of embroidered dresses; established an academy in his palace for the instruction of the young princes and nobles, and took great pleasure in being present at their exercises; raised one of those immense banks, which inclose the river Hoang-ho, and which he extended to a length of ten leagues. It was this prince, who, remembering in a dream a saying of Confucius, that the "Holy One was to be found in the west," sent ambassadors in search of that person and his doctrine, who, instead of Christianity, which is conceived to have better answered the interpretation of the words and dream, brought back the worship of the god Fo.

Increasing influence of the eunuchs.

In the course of this dynasty, especially under the reign of Voo-tee, the Chinese, after long wars and varying success, extended their empire both to the west and south; and drove the Huns and Tartars to a due distance from their frontiers on the north. But, towards the conclusion of the dynasty, particularly during the three last reigns, eunuchs began to multiply at court, and to acquire political influence with the emperors, which was the cause of exciting perpetual contentions in the government, and of encouraging the ambitious attempts of the petty princes. The empire was at length thrown into the utmost confusion during the reign of Hien-tee, a young and indolent prince; and in the year after Christ 220, was divided into three separate kingdoms, under as many independent sovereigns. Of those three reigning families, the Sho-han, Oey, and Ou, the first, which signifies the remnant of the Han, is considered as

		Yuen-tee	260		

The whole period of this short dynasty was a season of warlike commotion. The dominions of Heoo-tchoo enjoyed the greatest share of repose, through the exertions of two famous generals in his service, one of whom, named Quang-yoo, is worshipped as the Chinese Mars. Heoo-tchoo, however, who is reproached with being not so much a peaceable, as a cowardly prince, was attacked by one of his rebellious generals, Song-tchao, to whom he quietly surrendered the throne, and was contented to receive a small principality for his subsistence.

Kong-tee	419		

During the whole period also of this dynasty, a constant succession of wars and struggles for the empire prevailed; and excepting Voo-tee, who kept the petty princes in awe, few of the other sovereigns died a natural death, or without being first dethroned. In the course of this period, the northern armies began to evince their superiority over the more southern, both by their own native courage, and also by the assistance which they frequently derived from the Tartar tribes. Hence originated the division of China, during the four following dynasties, into

Voo-tee, the founder of this dynasty, whose first name was Lieoo-hoo, was of the lowest origin, and used to traverse the country selling shoes; but, at length, becoming a soldier, he attained to the command of a great army, and murdered the two last emperors of the former family. He fixed his court at Nan-kin, his native place; and is said to have possessed a figure and deportment inexpressibly noble and majestic. Long and bloody wars were carried on between the northern and southern empires, during the reign of Ven-tee and his rival Tay-voo-tee. The remaining sovereigns of this dynasty were noted for their horrid cruelties; and the two last mentioned were murdered by the prime minister, Siao-tao-tching, who afterwards took the name of Kao-tee, and became the founder of

During this dynasty, and in the reign of Voo-tee, appeared the atheistical philosopher Fan-shin, whose doctrine is said to be still privately entertained by many of the Chinese literati, and whose system was simply this, that all the events in the world are the result of chance, and that the soul dies with the body. About the same time, the prime minister Siao-yieuen, rose to distinction; a man of boundless ambition, who afterwards murdered the two last monarchs of the present race, and founded

* This appellation is written and accented in the Chinese language, so as to sound differently from the name of the fourth dynasty.

History.
A. D. 550.

The founder of this dynasty, who assumed the name of Voo-tee, was the most able of all its sovereigns; but became at length so fond of the Bonzes, that he resolved to become one of their order. The grandees of the empire in a manner forced him to resume the government, but he still continued to live after the manner of the Bonzes. Towards the latter end of his reign, he was seized and starved to death by the king of Ho-nan, one of his tributary vassals. During the existence of this dynasty in the south, the northern empire was divided into two kingdoms, the eastern and western, which were both much distracted between the patrons and the opponents of the Bonzes. Again it is recorded, that a prime-minister Shin-pa-sien, murdered the two last sovereigns of the reigning family; and, adopting also the name of Voo-tee, like the preceding usurpers, became the founder of

The princes of this dynasty are in general celebrated as wise and virtuous monarchs, friendly to learning, and attentive to the welfare of their subjects. It was in the reign of Ven-tee, that the night-watches were first intimated by the beating of a drum; a method which has continued to be observed in China ever since his time. The last named sovereign of this family having abandoned himself to a licentious life, was dethroned by Yang-kien, who afterwards assumed the name of Ven-tee, and founded

Union of northern and southern empires.

Ven-tee, seven years after his usurpation, reunited the northern and southern empires, which had continued distinct nearly 300 years, and of which the river Yang-tse-kiang had been the constant boundary. He was a prince of solid understanding, and the greatest temperance and moderation. He was strictly vigilant over the conduct of the administrators of justice; and made a regulation, which excluded merchants and mechanics from offices of state. He restrained the progress of licentious music, and other enervating amusements; and caused a portion of rice and other grain to be levied as part of the revenue, and to be preserved as a resource in seasons of scarcity. His son and successor Yang-tee, though he made his way to the throne by the murder both of his father and elder brother, and though much addicted to every species of luxury, yet made many useful regulations; repaired the great wall, which had fallen into decay, encouraged the progress of literature, and was the first who prohibited all his subjects, except the military, from wearing arms about their person. His successor was dethroned by Li-yien, one of the petty princes of the empire, who afterwards was called Kao-tsoo, and founded

Excellent emperor and empress.

Tay-tsong, the second prince of this dynasty, was one of the most renowned and virtuous of the Chinese monarchs. He was a great lover of learning, and is said to have instituted an academy in his own palace, at which 8000 scholars were instructed in all kinds of literature. He was a determined enemy to every species of bribery, especially in the administration of justice; and held all descriptions of diviners in the utmost contempt. It was in his reign, that certain Nestorian Christians entered China (of whom a more particular account will afterwards be given), and were not only permitted to preach their tenets, but received from the emperor a piece of ground in the capital, for building a place of worship. His empress was equally celebrated for her excellent qualities; and was the author of a book upon the due behaviour of women *in their inner apartments*. After her death, he admitted into his palace a young lady of singular beauty and talents, about fourteen years of age, named Voo-shee, who, after his decease, retired into a monastery of bonzesses, from which she was taken by his son and successor, Kao-tsong, and invested with the disposal of every thing in the empire. She proved a monster of ambition and cruelty, while she received from the infatuated emperor the title of "Queen of Heaven." She had been at first admitted into the palace as a concubine, and had experienced great favour from the empress. She soon, however, found means to have her benefactress divorced, on account of sterility; and, upon discovering, that the emperor still retained some affection for his discarded queen, caused her to be cruelly put to death. She sacrificed, in like manner, numbers of the royal family, who incurred her displeasure, or appeared to stand in the way of her plans. She was no less merciless to her own children; poisoned her eldest son, and banished the second, that she might raise the younger brother to the throne, whom she could more easily render subservient to her will. After the death of the emperor, she openly assumed, what she had long privately exercised, the absolute direction of affairs, and ruled the empire with the greatest ability, but with the most savage tyranny; cut off, without remorse, those nobles whom she suspected to be unfriendly to her interest; quelled insurrections, and detected conspiracies by her vigilance and resolution; kept her subjects in awe and submission, by the terrible vengeance, which she inflicted upon the disaffected and seditious; and supported herself firmly upon the throne, for the space of twenty-two years. At length, some of the boldest of the nobles, headed by one of her sons, burst into the palace; cut in pieces her attendants and confidants; and, while they trembled in her presence, intimated that her reign was at an end. She then calmly led her son to the throne, and retired to the

An ambitious and cruel princess.

apartments of the women, where she did not survive her deposition many months. Under the succeeding sovereigns of this dynasty, the empire was frequently thrown into the greatest confusion by the incursions of the Tartars, and the struggles of the tributary princes. The influence of the eunuchs, also, increased to such a degree, that, like the pretorian bands of Rome, they frequently disposed of the empire at their pleasure. In the reign of Tchao-tsong, a wise and valiant prince, their insolence became so intolerable, that the emperor entered into a plan with his counsellors to abolish their power for ever; but the eunuchs, having been apprised of the designs forming against their interests, came suddenly upon their sovereign with a band of soldiers, and hurried him into a remote apartment of the palace, where he was left under a strong guard, with only a hole in the wall for the conveyance of his food. By the courage of his prime minister, however, he was rescued from the hands of the rebels; and, having invited to his assistance a captain of banditti, named Shoo-ven, issued an order for extirpating the whole class of eunuchs, except thirty of the youngest, to be reserved for the most servile offices of the palace. His commission was faithfully executed by Shoo-ven; and many hundreds of them were put to the sword. The executioner, however, as if inspired with the ambitious spirit of those whom he had slain, murdered first the faithful prime minister, and afterwards the emperor himself; but permitted his son Tchao-siuen-tsong to reign for two years, when he assumed the sovereignty, and, under the name of Tay-tsoo, founded

Fourteenth dynasty.

During this, and the four following petty dynasties, a warlike Tartar nation, who inhabited the country, now called Leao-tong, established a powerful empire in the northern part of China, and proved very formidable neighbours to the Chinese princes. Mo-tee was dethroned by Tchoang-tseng, the son of the celebrated one-eyed general Li-ke-yong, who had received the principality of Tsin, on account of his eminent services in the reign of Hee-tsong; and by him was founded

Loo-tee	934	

Fifteenth dynasty.

Ming-tsong, though originally a foreigner, and only adopted into the Imperial family, was a truly excellent and pious prince; and was the author of a useful regulation, which excluded all eunuchs from public employments. His son in law, She-king-tang, by the assistance of the Tartars of Leao-tong, deprived Min-tee of his crown and life; dethroned his successor Loo-tee, and, under the name of Kao-tsoo, founded

Nineteenth dynasty.

The most celebrated prince of this dynasty was its founder Tay-tsoo, who checked the incursions of the

Tartars, and restored the tranquillity of the empire, and was distinguished by his generosity and humanity, his love of learning, and abhorrence of luxury. During the reign of his successors however, the Tartars of the East, though frequently repulsed, made uniform encroachments upon the Chinese dominions ; and were generally arrested in their progress, not by the force of arms, but by the promise of an annual pension or tribute. In the reign of Ning-tsong, the power of the Western Tartars arose under the famed Genghis-Khan, and, by their assistance, the empire of the Eastern Tartars were completely subdued. These victorious allies, however, soon began to extend their conquests at the expence of their Chinese friends ; and, under the voluptuous reign of Too-tsong, gained easy and speedy possession of the Northern provinces of the empire. They next advanced into the centre of the country with immense forces, seized upon the succeeding prince, Tee-hien, who was only an infant, and sent him into the deserts of Tartary ; compelled his brother Tein-tsong, who was next placed on the throne, to take refuge in the most southern parts of Quang-ton, where he died in the second year of his reign ; attacked his successor, Tee-ping, a child like his two predecessors, who was then on board his fleet under the care of his prime minister ; and, after a most sanguinary contest, in which 100,000 Chinese are said to have perished, either by the sword or the water, gained a complete victory, and terminated the power of the Song-family. The conqueror, called Ho-pee-lie by the Chinese, and Kulbay-Khan by the Tartars, afterwards assumed the name of Shee-tsoo, and founded

Accession f Tartar rinces.

Shee-tsoo, though he was the first foreign prince that governed the Chinese nation ; yet, by adhering as closely as possible to their ancient laws and customs, by his love of learned men, and his respect particularly to the memory of Confucius, by his uniform equity, and paternal tenderness towards all his subjects, he effectually reconciled them to his government. He even caused a proclamation to be issued at his accession, permitting all persons to continue in the same offices, which they had enjoyed in the preceding reign ; and to this day the reign of his family is styled by the Chinese, "the wise government." He was the author of the statute, which appoints, that there should be but one calendar throughout the empire, which should be compiled at court, and published every year. He was the first sovereign, also, who removed the royal residence to Pe-kin ; and, to prevent the frequent shipwrecks, which took place among the vessels employed in bringing to the metropolis, by sea, the tribute of the southern provinces, or in carrying on the trade of the empire ; he constructed the great canal, which extends nearly 1500 leagues, as will afterwards be more particularly described ; and, which, besides being one of the greatest wonders of the country, is one of the greatest benefits, which had ever been conferred on the Chinese empire. The succeeding princes of this dynasty were all distinguished by their private virtues, as well as their excellent government ; but both they and their Tartar followers, became gradually enervated by the softer climate and luxurious productions of China. Shun-tee particularly, though in other respects a prince of considerable talents, sunk into habits of the most effeminate indolence, and yielded himself entirely to the influence of the Lamas of Tartary, who filled his palace with female singers and dancers ; and introduced such a system of idolatry and debauchery, as at once enfeebled the courage of the Tartar captains, and rendered them contemptible in the eyes of the nation whom they had subdued. In the 14th year of the reign of Shun-tee, a Chinese of the name of Shu, who had been originally a servant in a monastery of Bonzes, put himself at the head of a troop of insurgents, made himself master of several considerable cities ; repeatedly defeated the imperial forces ; compelled the emperor to take refuge in Northern Tartary ; and, ascending the throne by the name of Tay-tsoo, founded

Bloody contests with the Tartars.

The founder of this dynasty ascended the throne with universal applause ; and is celebrated as a prince of the greatest piety and wisdom. The empire, however, did not long enjoy the state of tranquillity and order, which he had established ; and scarcely a single reign occurs in the course of this dynasty, which is not marked with the most bloody intestine commotions, or repeated inroads of the Northern Tartars. About the latter end of the reign of Shin-tsong, the Niu-tche, or Eastern Tartars, who had been reduced by the Western Tartars, in the time of Genghis-Khan, again recovered their strength, reunited their scattered principalities under one sovereign, and commenced a succession of attacks upon the empire of China, which terminated at length in its total subjugation. About the year 1617, the Chinese mandarins had conducted themselves with unjustifiable insolence towards the Tartar merchants residing in Leao-tong ; and had proceeded so far in their aggressions, as to put their prince to death, after having treacherously got possession of his person. Tien-ming, the son of the deceased king, entered the Chinese territories at the head of a powerful army ; but sent a proposal to the emperor, in which he engaged to withdraw his forces, upon receiving satisfaction for the injuries, which he had sustained. The mandarins, to whom the letter was communicated by the emperor, professed to hold its author in the utmost contempt, and disdained to vouchsafe any answer whatever ; which exasperated the Tartar prince to such a degree, that he vowed to sacrifice 200,000 Chinese to the manes of his murdered father. He marched an army of 50,000 into the province of Pe-tche-lee ; but, being checked in his progress by the Chinese forces, he

Origin of the Tartar invasion.

retired to Seao-tong, where he assumed the title of Emperor of China. Two years afterwards he drew the imperial forces by a stratagem into the wilds of Tartary, where he surrounded and cut to pieces the whole army; and, advancing with his victorious troops into China, destroyed a second army, which had been sent to oppose his progress. Under the reign of Hee-tsong, who was assisted by auxiliaries from Corea, by an Amazonian lady at the head of several thousand men from the province of Se-tchuen, and by Portuguese engineers from Macao, the Tartar prince was again compelled, for a short time, to evacuate his conquests. But having discomfited the neighbouring powers, who had taken the opportunity of his absence to invade his dominions, (and whose hostile demonstrations had probably tended, more than the prowess of the Chinese armies, to occasion his retreat,) he returned to the invasion of China with redoubled fury, gained possession of the city of Pekin, and commanded all the Chinese inhabitants, under pain of death, to shave their heads after the Tartar fashion; on which occasion, it is said, that several thousands of them chose rather to lose their heads, than their hair. After the death of Tien-ming, the leader of the Tartars, who was succeeded by his son Tay-tsong, a prince of a mild and compassionate disposition, the Chinese empire was so much distracted by rebellions in different quarters, that it was necessary to direct all the strength of the army to their reduction; and negotiations for peace were opened with the Tartar Prince, which appear to have been in some measure successful.

Reluctance of the Chinese to shave their heads.

Tien-tsong was succeeded in Tartary by his son Tsong-te, a prince of the most affable manners and polite accomplishments, who had been privately educated among the Chinese, and was intimately acquainted with their literature and customs. On these accounts, he was highly esteemed by many of the Chinese mandarins, who, disgusted by the temper of the old Emperor Hoay-tsong, which had been soured by the troubles of his reign, transferred their services to the Tartar court. In the meantime, every province almost in China was infested by bands of robbers or rebels, which were at last collected into two distinct armies; whose commanders, Lee and Shang, agreed to divide the empire between them. The former, after gaining various successes, and committing the most barbarous cruelties upon the adherents of the emperor, approached the capital, at the head of an army of 300,000 men. The city was strongly garrisoned, and might have resisted all the attempts of the usurper, but the troops of the government were divided into a multitude of rival factions, and filled with numerous partisans of the rebel general. The emperor himself, partly from the neglect of his officers, and partly from his own indolence, had been hitherto kept in extreme ignorance of the true state of affairs; and remained shut up in his palace, occupied in practising the superstitions of the Bonzes. When at last aroused to a sense of his situation, he found his capital betrayed to the enemy, his palace surrounded by his rebel subjects, his attendants and officers fled, and every avenue of escape shut up. Retiring in despair with his family, his prime minister, and a few faithful eunuchs, into a distant part of his gardens, they with one consent sought a refuge by death from the insults of the victor. The rebel seated on the throne, treated with the utmost indignity the dead body of the unfortunate monarch, when it was brought into his presence, and commanded the remainder of his family and adherents to be put to death. Every one hastened to secure himself from a similar fate, by making submission to the usurper, except Oo-san-hoey, the governor of Leao-tong, who obstinately refused to acknowledge his authority. Lee, (or Lie-tse-ching,) carrying with him the father of Oo-san hoey, invested the faithful viceroy in the capital of his province, shewed him his aged parent loaded with irons, and vowed to put him instantly to death, should he refuse to submit. The brave Oo-san-hoey, bursting into tears at the sight, fell upon his knees, and besought forgiveness of heaven, if he should still persist in his allegiance at the risk of his father's life, who approved the resolution of his son, and calmly submitted to his fate. Determined to avenge at once the death of his prince and his parent, he made application for aid to the Tartar sovereign Tsong-te, who instantly joined him with an army of 80,000, and compelled the usurper to retire to Pekin. Tsong-te died almost as soon as he had entered the Chinese dominions, after having committed the charge of his son and his empire to his brother A-ma-van. The young Tartar prince, Sun-shee, who was only seven years of age at the decease of his father, was speedily conveyed to Pekin, and welcomed by the people as their deliverer, with the most joyful acclamations. In the mean time, a grandson of Shin-tsong, and relative of the late imperial family, was proclaimed emperor at Nankin, under the name of Hong-kuang, and had the greater part of the nine southern provinces under his authority. The rebel Lee also was still at the head of a powerful army, which he basely employed rather in plundering and massacring the defenceless people, than in boldly contesting the throne with his competitors. Thus was the empire of China assumed by three separate and powerful claimants; and rendered, for several years, a theatre of war and bloodshed. The Tartar forces under the command of the three uncles of Sun-shee speedily triumphed over all opposition. Oo-san-hoey, assisted by the Tartar army, was indefatigable in the pursuit of the blood-thirsty Lee, compelled him at length to take refuge in the mountains of the west, with a few desperate followers; and, according to some accounts, slew him in an engagement with his own hand. One of the uncles of Sun-shee was then dispatched to the south against Hong-kuang, who was driven from his capital, taken prisoner in his flight, and put to death on the spot, or, according to some accounts, afterwards strangled at Pekin. He is said to have been an amiable prince, who had been carefully educated by the former emperor; and who, as the last refuge of the Chinese, had been urged, against his inclination, to accept a crown, which he had not the power to maintain. Sun-shee, remaining sole master of the empire, ascended the throne by the name of Shee-tsong, and founded

Shin-tsoo-gin or Kang-hee .	1662	Kia-king	1796
Shee-tsong-hien or Yong-tching	1723		

Twenty-second dynasty.

During the space of ten years after the accession of this dynasty, new claimants, connected with the former family, continued to raise the standard of resistance; and even governors of provinces, without any personal views to the sovereignty, obstinately refused to submit to the Tartar sway. In the province of Se-tchuen Long-voo, or Jan-van, a descendant of the former dynasty was proclaimed emperor of the Chinese: and was supported in his pretensions by the celebrated sea-captain Tchin-tchi-long, or Ikoan, of whom the following account is

Celebrated sea-captain.

given. He was born of very obscure parents in the province of Fo-kien, and went to Macao to make his fortune among the Portuguese, where he became a convert to Christianity, and took the name of Nicholas Gaspard. Thence he repaired to Japan, where he entered the service of a wealthy merchant, and became at length the commander of his trading vessels to Cochin-China, Camboia, and other places. While he was on a voyage at Camboia, having heard, that the merchants, with whose commodities he had been entrusted, had been carried off by a pestilence which raged in Japan, he immediately applied to his own use the property in his hands, purchased a number of armed vessels, and became the most formidable captain of pirates, that had ever been known in the Chinese seas. In alliance with another commander, he plundered all the ships, without distinction, which came in his way, and bid defiance to all the fleets of the empire. The emperor, unable to reduce these naval chiefs by force, wrote, at the same time, a letter to each of them, expressing his high sense of his valour, and of the services which he might render to his country, inviting him to join the imperial navy in subduing the other piratical fleet, and promising him in recompense the office of captain-general of the sea-coasts, and admiral in chief of the sea-forces. Tching-tchi-long, though he suspected the artifice, yet, depending upon his strength and good fortune, instantly made sail to attack his fellow pirate, whom he vanquished and put to death, after a desperate engagement; took the greater part of his ships and crew into his service; and thus, become more powerful than ever, boldly advanced to meet the imperial fleet, which, instead of attacking, as was intended, the remaining pirate, weakened, as they expected, by his conflict with the other, were glad to congratulate him upon his success; whilst by virtue of the emperor's letter, he immediately commenced the functions of high admiral, and required all the trading vessels of the empire to receive their passports from his hand, for which he exacted enormous sums, to the great detriment of commerce and of the maritime provinces. By bribing the favourite eunuchs and chief officers at court, he prevented the numerous complaints against him from reaching the ears of the emperor; and raised himself to such a degree of power, that no one dared to question his actions. On one occasion he went ashore at Canton, where the imperial officers had withheld a part of his revenue, as admiral of the fleet; entered their populous city with only 6000 of his men; erected a tribunal in one of the public squares; and, having summoned the officers in question, together with some lawyers, into his presence, obliged them instantly to pay him the money which he required, gave them receipts in form, and returned to his fleet without any obstruction. Upon the death of the Emperor Hoay-tsong, he might have seized upon the crown with greater prospect of success, than either of the rebels Lee and Shang formerly mentioned; and it is said, that in the event of his making such an attempt, he had a promise from the Dutch traders at Formosa to assist him with all their forces. But he transferred his allegiance to Long-voo, as the only remaining representative of the imperial family; and rejected with scorn all the attempts of the Tartar monarch to gain him to his interests. After engaging the armies of that prince in several bloody battles, with varying success, he was taken prisoner and sent to Pekin; but, as his son was still at the head of his powerful fleet, he easily found means to secure his own safety, by engaging to support the Tartar interest. Long-voo, either unable to stand without the aid of Tching-tchi-long, or, as others pretend, having been betrayed by his means into the hands of the other party, was deprived at once of his life and crown. Still the provinces of Quang-see and Quang-tong refused to submit.

Opposition to the Tartars.

Against the latter, where a young prince of the late imperial family had been proclaimed, one of the uncles of the Tartar emperor, named Peli-poo-wang, was sent with a powerful army in the character of viceroy. The Chinese troops never attempted to face the enemy; but, according to some authors, the city of Canton stood a twelvemonth's siege with great spirit; and was, on that account, given up by the Tartar general to be plundered, three whole days. The young emperor and his adherents were put to death; and the inhabitants subjected to every species of cruelty and insult. The rest of the province was soon reduced, except the town of Shao-king, where another young prince, named Yoong-lo, had been proclaimed emperor by the viceroy of Quang-see, Thomas Kioo, and the late generalissimo of the Chinese army, Luke Shin, both of whom were Christian converts and brave commanders. The chief counsellor of this prince was a Christian eunuch named Pan-Achilles, by whose means the Jesuit missionary Andrew Koffler was brought to instruct the monarch and his family in the truths of Christianity, and it was hoped that he might one day prove the Constantine of China, by which name he was in that view baptized. The Tartar army, after the reduction of Canton, marched without delay against this new competitor, but were engaged with great intrepidity, and completely routed by Kioo and Shin. The report of this victory, and of the election of a new emperor, spreading through the neighbouring provinces, revived the courage of the Chinese; and a new army, appearing in Fo-kien, gained several cities from the Tartars; while Tchin-tchi-kong, called by the Dutch Coxinga, son of the celebrated Tchin-tchi-long, taking part with the imperial family of China, made great progress in subduing the towns on the sea-coast. His success, however, was of short duration; and, having received a total defeat from the Tartars, he was driven out of China, and obliged to retire to his fleet. New armies sprung up in every quarter against the conquerors; and battles were fought with various success. The viceroy of Kiang-see shook off the yoke, and defeated the Tartars in several engagements. Two chiefs in the northern districts, whose names were Ho and Kiang, uniting their forces, gained a great victory over the Tartars; and kept the field for a considerable period without opposition. Yoong-lo resisted all their attempts upon the city of Shao-king; and, having put himself at the head of his troops, repulsed them a second time from the frontiers of his province.

Formidable opponent to the Tartars, and bloody oppressor of the Chinese.

But the most terrible of all their opponents was a chief named Tchang-hien-tchang, who was rather a general murderer and robber, than a competitor for the crown, or a commander in any interest. He completely expelled the Tartars from the western provinces, where he is said to have committed barbarities altogether incredible; and governed everywhere in the most tyrannical and ferocious manner. If any one under his jurisdiction committed an offence of the most trivial nature, he commanded the culprit, and all who inhabited the same street, to be put to death. He caused 5000 eunuchs to be murdered, because one of them refused to acknowledge him as emperor; and butchered, in like manner, 10,000 learned men, because he regarded them as hostile to his pretensions. Upon leaving the capital of Se-tchuen, he ordered the inhabitants to be led out of the city in chains, and to be massacred in the fields, to the number of 60,000. He called upon his troops to murder all their wives, because they were an incumbrance in time of war, and gave them an example, by cutting the throats of 300 of his own women. He pretended to be a friend to the Christians, and to have received a commission from heaven to root out every other system of faith. Advancing to meet the Tartar army in Shen-see, he was shot through the heart with an arrow, while he was reconnoitring unarmed in the front of his troops; upon which, his soldiers immediately dispersed, and submitted to the Tartar emperor. By stratagem rather than by force, by sowing divisions among the Chinese commanders, and by the effect of promises and bribes, the Tartars succeeded at length in regaining all the places which had revolted; and Yoong-lie, being hard pressed in his capital, was compelled to take refuge in the court of Pegu; but was afterwards delivered up at the demand of Shee-tsong, by whom he was ordered to be strangled at Pekin. It was chiefly owing to the wise policy and humane conduct of A-mavan, the uncle and guardian of the young Tartar prince, that the Chinese were so easily subdued, and so completely reconciled to the authority of the new dynasty. Shee-tsong faithfully adhered to the system, which his uncle had adopted in governing the empire. He ascribed his great success, not to the number or valour of his troops, but to the will and favour of heaven; a sentiment exactly coinciding with the Chinese creed, and furnishing them with an excuse, which they plead to this day, for submitting to a foreign yoke. Instead of shutting himself up in his palace, according to the custom of the Chinese emperors, he began his reign with shewing himself much in public, and giving his subjects free access to his presence. He gained their attachment, above all things, by the respect which he paid to their whole system of government, laws, and customs. Nothing was changed, that could be regarded as of any importance; but, on the contrary, the conquerors conformed almost in every respect, to the manners of the vanquished; married into Chinese families, studied the Chinese language, adopted the Chinese dress, and mixed completely with the common mass. The ablest Chinese were appointed to the civil departments, in preference to Tartars; the superstitions of the country were upheld and encouraged; and the people were scarcely sensible of any change having taken place in the administration of public affairs. The army alone was reserved for the Tartars; and is still chiefly composed of the countrymen of the emperor.

Wise policy of the Tartar prince.

Jesuit missionaries patronized.

Shee-tsong greatly patronised men of learning; and shewed extraordinary favour particularly to the persons employed in the Jesuit mission to China. Adam Schaal was made president of the tribunal of mathematics, and intrusted with the reformation of the calendar, an office which had been held by the Mahommedans nearly 300 years. This eminent Jesuit was honoured by the emperor with the appellation of *Ma-fa*, "my father," and enjoyed the special privilege of presenting his petitions into his own hands, without subjecting them to the examination of the usual tribunals. About eight years after Shee-tsong had taken the reins of government into his own hands, the renowned sea-captain Tching-tching-long, or Coxinga, again appeared upon the coast of China with his numerous fleet, and at length laid siege to the city of Nan-kin; but his army, having devoted themselves to feasting and amusements for three days, in celebration of his birth-day, the besieged embraced the opportunity to make an attack upon his camp at midnight, while the soldiers were oppressed with wine and sleep, and drove them to their ships with great slaughter. Enraged by this defeat, he pursued the Tartar fleet, destroyed a number of vessels, took 4000 prisoners, and after having barbarously cut off their noses and ears, he sent them all ashore, where they were still more barbarously put to death by their own government, as a punishment for having yielded to a rebel, but, in reality, as a mean of concealing the disgrace of the discomfiture. Coxinga, after this victory directed his course to attack the island of Formosa, which was chiefly occupied by Dutch traders; and, after a blockade of four months, compelled them to surrender from want of provisions. The Dutch, however, were permitted to carry off their property; and the part of the island, which had been occupied by the Chinese, was formed by the pirate chief into a small kingdom.

Death of the Emperor Shee-tsong.

The emperor Shee-tsong, about the 17th year of his reign, while he was only 24 years of age, died of grief on account of the loss of one of his queens, after having made an attempt to deprive himself of life. While he was upon his death-bed, he called four of his chief mandarins into his presence, and charged himself before them with various faults during his government, with ingratitude to his most faithful minister, neglect of the counsels of his mother, affection to the eunuchs, extravagance in vain curiosities, and inordinate attachment to the late queen. He next appointed them guardians of his youngest son Kang-hee, whom he declared his successor, and who was then only eight years of age. Then, calling for his imperial robe, he covered himself with it in his bed, and instantly expired.

Accession of Kang-hee.

The guardians of the young monarch devoted themselves to the welfare of the empire. They began their administration with wisely expelling all the eunuchs from the palace except about 1000, who were reserved for performing the lowest offices. They next published an edict, requiring all the inhabitants of the sea-coast to withdraw three leagues from the sea, and all maritime commerce to be abandoned; which impaired, indeed, as they are supposed to have intended, the power of Coxinga, but which also completely ruined an immense multitude of Chinese families, who subsisted by fishing. They next issued a severe edict against the Christians, who were soon after compelled to leave the empire, as will afterwards be more particularly related. Oo-san-hoey, who had invited the Tartars into China, and who had received from Shee-tsong a district in Shen-see, with the dignity of king, is represented by the Chinese historians, as having soon repented his error in calling the Tartars to his aid, saying that "he had sent for lions to drive away dogs." In the 12th year of the emperor Kang-hee, he openly raised the standard of rebellion, made himself master of several western provinces, and exercised the prerogatives of the emperor. At the same time, two of the southern princes declared war against the Tartar government, and were joined by Tching-tching-may, the son of Coxinga, and now king of Formosa. But these insurgents soon quarrelled with each other, and made their submission to Kang-hee; while Oo-san-hoey, after sustaining several successive defeats, sunk under the load of years, the fatigues of war, and the pressure of grief and disappointment. His son Hong-hoa, nevertheless, supported his father's views, and assumed the title of emperor; but was soon reduced to such extremities by the Tartar generals, that, to avoid falling into their power, he put himself to death. About this time, a dreadful earthquake was experienced in the northern parts of the empire, and at Pekin alone, 300,000 persons are said to have been buried in the ruins of their habitations. Kang-hee, who, even in his youth, had discovered the greatest talents for governing, as soon as the different insurgents had been completely suppressed, made a visit to his native dominions in Eastern Tartary, accompanied by his

Intestine commotions.

family, his court, and an army, it is said, of 70,000 men. He made a similar visit, during the following year, to Western Tartary; and continued annually to repeat these expeditions, under the pretence of hunting, but in reality for the purpose of keeping his troops in exercise, of displaying the grandeur of his court, and of awing the vassal princes, who were required to join him in his progress.

Influence of the missionaries.

By the assistance of two of the missionaries, Father Gerbillon and Pereira, the boundaries between the Russian and Chinese dominions were amicably defined in the year 1689. In 1693, the emperor was restored by the medicines of the missionaries from a dangerous attack of fever; and in gratitude for their services in this instance, as well as through the influence of Gerbillon and Pereira, who instructed him in the European sciences, he extended a greater degree of toleration to the Christian religion, and conferred several important privileges upon the Jesuit residents in Pekin.

Survey of the empire.

In the year 1707, the emperor employed these learned missionaries to make a map and survey of the empire; a work which they accomplished with great labour in little more than ten years, and which does honour both to the prince who planned, and to the persons who executed the vast undertaking. In 1722, the emperor Kang-hee, after having established his empire in profound peace, and done more for its improvement than any sovereign who had ever filled the throne, died suddenly in the 69th year of his age, and the 60th of his reign.

Death and character of Kang-hee.

He was a prince of a truly enlarged mind, and possessed of many estimable qualities; indefatigable in his application to public affairs; cautious and discerning in the choice of his ministers; singularly frugal in his personal expenditure, but munificent and affectionate towards his people; an anxious promoter of peace, both in his own dominions and among neighbouring nations; friendly to the arts and sciences, which he cultivated himself with distinguished success; addicted to an active mode of life, and skilled in the military exercises of his nation; uniting in his personal character the most manly corporeal and mental endowments, and in his political administration, the tenderness of a parent with the firmness of a prince.

Accession of Yong-tching.

He was succeeded by his fourth son, whom he had nominated to the throne, and who assumed at his accession the name of Yong-tching, which signifies "perpetual peace." The new emperor, entering upon his function in the prime of life, applied himself with the utmost assiduity to the discharge of his weighty duties. He is said to have employed whole days and nights, without interruption, in framing useful laws and regulations; and to have been particularly attentive to receive and answer the numerous memorials presented for his inspection. The most effectual way to gain his favour was to propose some scheme, which tended to advance the public good, or to provide relief for his subjects in times of calamity. Except his thirteenth brother, he had no confidents in his measures; but governed wholly of himself, and with the most absolute authority.

Persecution of the Christians.

He is said to have been endowed with great wit and eloquence, but to have been less addicted to scientific pursuits than his father. He began his administration with issuing the most severe edicts against the Christians, whom at length he utterly proscribed and banished from his dominions; and, notwithstanding the excuses, which may be alleged for this measure, from the misconduct of the missionaries, it is impossible to vindicate the cruel persecutions, which he instituted against the native converts, and in which so many of the noblest families were miserably destroyed.

Dreadful earthquake.

In the year 1731, another destructive earthquake was experienced in the northern provinces, in consequence of which 100,000 persons were said to have perished in Pekin, and a still greater number in the neighbouring country. The emperor was residing at the time in one of his pleasure houses, about two leagues distant from the metropolis, and was sailing in his barge upon the canal in his gardens, when the shocks commenced. His palace was instantly reduced to a heap of ruins, and the emperor, who had fallen on his knees at the sight, afterwards published an edict in the usual stile, ascribing the calamity to the wrath of heaven against himself, for his offences and want of care in governing the people; commanded an estimate to be made of the losses, which had been sustained; and issued large sums for the relief of the sufferers.

Accession of Kien-long.

Yong-tching died in the year 1736, after a reign of thirteen years, and was succeeded by his son Kien-long, who ascended the throne without opposition, though he had not been regularly declared by the late emperor as his successor. He had hitherto devoted himself entirely to literary pursuits, and was little acquainted, at the time of his accession, with public affairs; but his mild and benevolent character speedily attached to him the affections and applause of his people. In 1746, new decrees were issued against the missionaries, a few of whom, however, were still permitted to reside at Pekin, on account of their services in matters of science. In 1753, an insurrection was excited among the Eleuth Tartars, by a powerful prince named Amoursana; but the approach of a Chinese army compelled him to take refuge in the deserts of Siberia, where he died a few years afterwards. Kien-long sent a message to the Russians, requiring the dead body of Amoursana to be delivered up to him, that it might be subjected to the customary penalties, for the intimidation of others; but the Russians, while they shewed the body of the prince to the Chinese commissioners, in order to satisfy them of his decease, refused to commit it into their hands, as their laws, it appears, prohibit any exposure to indignity of the remains of unfortunate persons, who may take refuge in their dominions. In the year 1770, about 50,000 families of the Tourgouth Tartars, in the Russian territories, migrated to the frontiers of China, and were afterwards followed by an additional number, which made the whole amount to nearly half a million of souls. The Chinese monarch was so much gratified by the accession of so many new subjects, and by the testimony of approbation which it afforded of his government, that he caused a monument of stone to be erected in commemoration of the event, with an inscription in four different languages. In the year 1782, the emperor shewed his vigilance over the administration of public affairs, and his regard for the welfare of his subjects, by punishing a great number of persons of the highest rank, who had been found guilty of embezzling the revenues, and oppressing the people, while he diminished the amount of taxes upon the lower classes of the community, and promoted the learned men throughout the empire according to their merit.

Insurrection of the Mahometan tribes.

In the year following, the tranquillity of the empire was interrupted by a dissension among some tributary Mahometan tribes on the western frontiers; and the more turbulent families, to the number of 10,000, having been punished by the Chinese governor with banishment to a more distant residence, they excited the tribes, among whom they had retired, to throw off the yoke of the Chinese emperor, and extended the spirit of revolt to the confines of Bucharia. Having secretly secured adherents among the people, where they had formerly resided, and procured a considerable quantity of military stores, they placed themselves under the command of a rebel chief, who had formerly experienced the emperor's clemency, and erected a strong fort in a situation that was deemed inaccessible. Their commander was defeated at the head of 10,000 men, and taken prisoner by the Chinese, before the Mahometans had collected their forces. But the chiefs who came to their assistance, to the number of the different tribes, having found themselves, when united, not less than 100,000 fighting men, immediately commenced offensive operations. The Chinese governor injudiciously sent out small detachments, which were successively cut to pieces; and the insurgents, losing no time in the attack of fortified places, penetrated into the midst of the empire, destroying every thing in their progress with fire and sword, seizing upon the public magazines and treasures, and sacrificing the governors who ventured to oppose them. A numerous army, however, was speedily marched against them, under the command of the prime minister; and they were compelled to retreat to their stronghold, which was protected by a considerable river and lake in the front, and in the rear by a very steep and lofty mountain. While they imagined themselves secure in this retreat, the Chinese commander caused the course of the river to be turned by his numerous workmen, and his troops to advance to surround the lake. The insurgents, being thus at once deprived of their strongest protection, and regular supply of water, were reduced to the greatest extremities. After enduring the torments of thirst for the space of three days, they adopted the desperate resolution of putting to death the useless persons among them, and of cutting their way through the Chinese army. They were completely overwhelmed in the daring attempt, their fortress taken by storm, and the whole of its defenders put to the sword, except a few of the leaders, who were afterwards executed at Pekin. This victory was followed by an order from the emperor to exterminate the whole nation, excepting those who were under 15 years of age, who were to be distributed as slaves among the Mahometan tribes, that had remained faithful to the emperor. This barbarous decree was rigorously carried into effect, and a tract of country, above 100 leagues square, containing 1000 towns and villages, was converted into an empty desert.

Destructive inundation.

In the year 1788, while the emperor, though now at the age of 78, was engaged in his usual recreation of hunting in the deserts of Tartary, a sudden inundation descended from the mountains, and flooded the whole adjacent country. It was with difficulty, that Kien-long gained a small elevation, where he passed a whole day without food, till a slender bridge was thrown across the hollow, by which he succeeded in saving himself, though a great number of his attendants were sweeped away by the torrents.

British embassy.

In the year 1793, a splendid embassy, under Lord Macartney, a nobleman of distinguished talents and accomplishments, was sent by the king of Great Britain to the Emperor of China, with a view to establish a more direct intercourse with that immense empire, and to secure more extensive commercial privileges for the British nation. The embassy was received by the Chinese government with every mark of respect; but completely failed in attaining the desired object. This want of success has been ascribed to various causes; to an imprudent assertion in an English journal on the subject, which found its way to China, and awakened the suspicion of its rulers; to the refusal of Lord Macartney to observe the established ceremony of prostration before the Chinese emperor; to the dread of Jacobin principles, which had already been introduced into China, and which augmented the aversion of the government to all European settlers; and to an oversight of the British ambassador, in not having treated, in the first instance, with the Ho-tchong-tang, or prime minister of China, whose influence is understood to be greater than that of the emperor himself. But, while each of these causes may be allowed to have had its weight, the true reason is unquestionably of a more general nature; and must be sought in the spirit of the Chinese people, proud, contemptuous, and suspicious, towards the inhabitants of every other country. This was sufficiently demonstrated in the fate of the Dutch embassy, which entered China with similar views in the following year. Though they carefully attended to every circumstance, which they supposed their predecessors to have overlooked, and meanly complied with the most humiliating requisition on the part of the Chinese; they were neither treated with so much respect as the English, nor were they, in the smallest degree, more successful in their object. All that they obtained was a sight of the emperor, a few trifling presents from his hand, and an exemption of the ship, which conveyed their ambassador, from the payment of any duties upon its cargo.

Dutch embassy.

Abdication of Kien-long, and accession of Kia-king.

In the year 1796, the Emperor Kien-long, according to a resolution which he had long entertained, abdicated the throne in favour of his son, after a reign of 60 years, and died in the year 1799, at the age of 89 years, with the character of an enlightened, humane, pacific, and prudent prince. He was succeeded, according to his own appointment, by his seventeenth son Kia-king, who had then attained the age of 40 years; but of whose reign and character, from the want of intelligence from China, we can present only a few detached circumstances. Immediately after the death of the old emperor, the prime minister, from some cause which is not known, was brought into disgrace, and compelled to become his own executioner. By accounts received from Canton, in the beginning of the year 1802, it is known that a strong and well-disciplined body of Tartars had made an incursion into China in the year 1800; an invasion which excited universal terror, especially as it was connected with serious internal commotions. Several districts were in arms at the same moment; but the imperial troops, by a prompt movement, brought the insurgents to action before they could be joined by the Tartars, and routed them with immense slaughter.* One of those severe droughts, which are so frequent in China, had prevailed about the same time in the eastern districts; and the natives had been reduced to the necessity of abandoning large tracts of country in quest of food, while the most benevolent exertions on the part of the emperor had not been able to impart much relief. The Chinese government, it was also learned by the same intelligence, having discovered, that the greatest evils result from the abuse of opium, entirely prohibited the importation of that article into the empire.

In 1804, intelligence was received in Europe, that another serious rebellion had broken out in the western provinces of China, and had even extended to that of Canton, where a descendant of the former imperial family had appeared at the head of 40,000 men, who were all animated by a prophecy current in the country, that the present Tartar dynasty was to be overturned in the course of that year. The emperor had issued an edict,

---

* A specimen of a Chinese Gazette, during this expedition, is published in Sir G. Staunton's translation of the penal code of that empire.

Success of the missionaries, and proscription of Christianity.

Vaccination introduced.

permitting the Roman Catholic missionaries to reside in any part of his dominions, within 20 miles of his court; and some thousands of children, with a few adults, had been baptized. In 1805, they are said to have had not less than 64 Christian seminaries of education, chiefly in the province of Se-tchuen; but, in 1806, Christianity was again proscribed; a Catholic missionary in Pekin was condemned to perpetual imprisonment; a number of civil and military officers were subjected to punishment, for permitting or aiding the labours of the missionaries; all the native converts were sent into banishment or slavery, and their books, papers, and printing blocks publicly burned. The truths of revelation, however, had been taught in numerous churches; and are supposed to have made impressions upon the minds of the natives, which even the persecutions, to which they have been exposed, will not speedily efface. About the same time, Sir George Staunton succeeded, with the assistance of Mr Pearson, surgeon to the British factory at Canton, in establishing the practice of vaccination in that populous city. The virus was obtained from Manilla, through the medium of the Spaniards. Mr Pearson wrote a concise treatise on the discovery and the mode of operation, with figures of the vaccine pustule; of the arm, with the proper place of puncture; of the lances charged with the matter, &c. This treatise, the first English work published in China, was translated by Sir G. Staunton, into the language of the country, and was gratuitously distributed at the expence of the East India Company, with the assistance of a Chinese surgeon. So far have the Chinese overcome their prejudices against European customs in this instance, that a general inoculation for the cow-pox took place in Canton, and a large subscription was raised by the natives, for establishing an institution in that city, by means of which the matter may be disseminated into every province of the empire.

Misunderstanding between the Chinese and British at Canton.

In the month of October 1806, a serious misunderstanding was occasioned between the Chinese government and the British factory at Canton; which originated in a scuffle on board an East India ship, between a native of the country and one of the crew, in which the former received a blow from a handspike, which afterwards occasioned his death. The Chinese government demanded, that the Englishman should be given up for capital punishment, or at least another of the same nation in his place, according to the laws of their country. But the offender had absconded, and all the British sailors denied any knowledge either of the deed itself, or of the person who had been the perpetrator. This answer, however, did not satisfy the Chinese; and all the British subjects were ordered to go on board their ships, and to quit Canton without delay. But the English commanders, having expostulated strongly upon the injustice of these measures, and supported their representations with some valuable donations to the relations of the deceased, the matter was at length amicably adjusted, and the usual intercourse again restored. In all the transactions, which occurred during this season of partial hostility, a Portuguese priest, named Father Rodrigo, who acted as interpreter to Admiral Drury, bore a very active and prominent part. This person, possessed of great courage and enterprise, had, previous to this event, succeeded in making his way, under the disguise of a Tartar, to the city of Pekin; and, after residing a considerable time in that capital without being discovered, returned in safety to Macao. This clandestine visit afterwards becoming known to the government at Canton, the Chinese mandarins expressed the strongest indignation, on account of the imposition and insult which had been practised upon them; and their resentment against the offender was rendered doubly inveterate, by his zealous interference in support of the British interests, especially by his spirited conduct upon the occasion of Admiral Drury's visit to Canton with the armed boats of his fleet. When the Chinese opened a fire from their fort and war boats upon the admiral's barge, Rodrigo stood erect upon the stern sheets, and, taking his cowl in hand, cheered with three loud huzzas; intending, as the Chinese alleged, and as was probably the truth, to incite the seamen to an immediate attack. The Chinese silently remarked his hostile demeanour towards them in the whole course of the dispute, and determined to seize the first opportunity of inflicting vengeance. As soon, therefore, as the British ships and troops had taken their departure, the father was treacherously enticed beyond the Portuguese boundaries, and carried prisoner to Canton; where the Chinese, glorying in the possession of their captive, unequivocally evinced their determination to make him atone, with his life, for the insults, which he had offered to the dignity of their empire. The Portuguese government, however, at Macao, feeling the necessity of protecting their subjects, and perceiving, that nothing but an appeal to force could effect the liberation of Rodrigo, commanded a ship of war and an armed brig to be moored, as close as the water would admit, to the two neighbouring Chinese forts; and, at the same time, marched their troops out of Macao, to invest the fortresses on the land side. Mr Roberts, also, the senior British supercargo, issued orders to all the company's ships to suspend their intercourse with the shore, and to prepare for such offensive measures as might appear requisite. These arrangements having been made, the Father was demanded in due form, with an explicit declaration, that unless he was delivered up without injury, and without delay, the Chinese forts should instantly be assaulted, and every man in the garrisons made responsible, with his life, for the safety of Rodrigo. The Chinese officers, whose unreasonable caprices require to be occasionally met with proper firmness, perceiving the determination of the Portuguese to carry their threats into execution, prudently acquiesced in the demand; and Rodrigo was triumphantly restored to his freedom and friends.

Their jealousy of the British.

It is asserted, that, notwithstanding the restoration of our commercial intercourse at Canton, the principal mandarins of that place have conceived a rooted prejudice against the British, which may not easily be removed; that they attribute every misfortune which befals any of their people in their transactions with us, to a systematic intention on our part to do them an injury; and that, upon the slightest pretext being afforded for complaint, they represent the matter to their superior tribunals in the most exaggerated form.

State of the Chinese government.

Five emperors of the Tartar race in succession, and all of them men of good understanding and vigorous minds, have now continued, without interruption, to rule over the Chinese empire; and have thus, it may be supposed, completely established their family in the supreme power. Recent occurrences, however, begin to indicate a more unsettled state of things in that country, and at least to shew, that the administration of so vast an empire is becoming daily a more difficult task. The Tartars, increasing in security, have become less attentive to conciliate the Chinese; and all the high offices are filled with the countrymen of the sovereign. It is suspected, that the government entertain a design of introducing the Man-tchoo language into general use, instead of the Chi-

[illegible], as great attention has been paid to its improvement, and as all the children, one of whose parents is of Tartar descent, have been expressly required to be instructed during their infancy, and to pass their public examinations, in the Man-tchoo tongue. The Emperor of China, like all oriental princes, shews no tendency to become indigenous to his adopted soil, but continues invariably attached to his native cast, and systematically favours his countrymen in every possible instance. The Tartars in China, it has been asserted by an eye witness, thus continue, from prince to peasant, to preserve their native character distinct, and to hold the subjugated Chinese in the utmost contempt. These, on the other hand, are represented as daily becoming more dissatisfied with the imperious manners of their conquerors, whom they heartily hate, while they are obliged to submit to their sway.

Power of the pirates.

A kind of piratical republic has been gradually forming upon the coasts, which, since the year 1805, has become extremely powerful. The number of the rebel vessels has been stated, by recent accounts, as not less than 4000; of which the largest are about 200 tons burden, carrying from 200 to 300 men, and from 12 to 20 guns; while the smallest are about 30 tons, with 50 or 60 men. In the beginning of the year 1810, they even attempted to blockade the port of Canton; and though they have not yet penetrated into the interior of the country, they are said to have numerous partizans in every quarter.

Seditious societies.

During the last twenty-five years, there has existed in China, particularly in the southern and western provinces, a kind of sect or association of disaffected persons, who furnish the rebels with all necessary intelligence. This association is named Thian-thee-ohe, which signifies "heaven and earth united:" and its members are extremely numerous. They know each other by private signs, such as the manner in which a cup of tea, or a pipe of tobacco, is offered and accepted. In the form of initiation, the new member is placed between two naked sabres, which are crossed over his head; and, in this position, he solemnly swears rather to perish than to betray the secrets of the society. A few drops of blood are then drawn from him, and from the person who administers the oath, which are mingled in a cup of tea, of which both parties partake. The great principles of this body are, the equality of all men, and the obligation of the rich to communicate of their abundance to the poor. In the year 1804, not less than nine provinces of the empire were disturbed by the machinations of these levellers; and their numbers daily increased to such a degree, that many of the more wealthy natives had become members of the association, and surrendered a part of their property to preserve the rest. Those, who resisted their influence, and refused to make such a compromise, were often secretly seized, and kept as prisoners, and even threatened with death, unless their friends should procure their release, by depositing a sum of money in a place appointed. A sect of a similar description exists in the northern provinces, under the name of Pelin-Kias, which signifies "enemies of foreign religion;" and which is founded upon discontent with the existing government, and dislike of a foreign dynasty. These associations obtain numerous partizans among the lower classes, who are often rendered desperate by their extreme indigence; and, in some districts, their members have abandoned themselves to the most daring excesses, and even to open revolt. The government have made great exertions to suppress these seditions; and it is said, that not less than 4000 persons had been capitally punished, within a very short period, on account of those practices. In 1798, one of their chiefs was proscribed by public proclamation, and a price of 10,000 piastres set upon his head; but he took refuge in the island of Java, where his principles have made great progress among the Chinese residents; but whom the dread of the European authorities has hitherto restrained from committing the excesses, to which their system has often given rise in China. By a recent edict of the Chinese government, all who were detected as members of the Thian-thee-ohe association, were condemned to have the tendons of the right foot cut across, and to have the left cheek marked with a red-hot iron: but, if farther convicted of having been engaged in any disturbance, they were sentenced to be capitally punished, by being beheaded. The people, however, in general, as long as they can easily procure their portion of rice, and a few savoury sauces, are in no temper for a revolt against their government: and hence it is the principal care of the latter to provide magazines throughout the empire, to serve as a supply in seasons of scarcity or famine.

Recapitulation of the history.

From a short recapitulation of the principal facts and events recorded in the Chinese annals, it may be seen, at one glance, that the boasted antiquity, extent, civilization, and tranquillity of China, have been too easily admitted by Europeans, and are clearly incompatible with the most authentic historical documents of that nation. From these it appears, that the greater part of the cities of China have been founded posterior to the dynasty of Tsin, about 250 years before Christ; that the empire, about 800 years before the Christian era, was composed only of the provinces of Honan, Shan-see, Pe-tche-lee, Shan-tong, and a small district in Shen-see, while the rest of the country was in the possession of barbarians; that the province of Se-tchuen was occupied by savage tribes, who were not subjected till the year 206 before Christ; that the philosopher Men-tse, who flourished 336 years before Christ, expressly declares, that the people of the kingdom of Tsoo, that is of the province of Hoo-koang, were at that time a savage race; that Quang-see was inhabited by barbarous hordes named Yue, the ancestors of the Miao-tse, who still exist in its mountainous districts, and that the lower parts were not subdued till the year 223 before Christ; that Koei-tcheoo was not reduced till the year 206 before Christ, and Yunnan not until the 7th or 8th century of the Christian era; that the kingdom of Oo in Kiang-nan was destroyed by the people of Yue and Tsoo in the year before Christ 473, but not subjected by the Chinese sovereigns till 200 years after; that Kiang-see, situated between the people of Yue and Tsoo, and the constant theatre of their wars, was not subjugated till 250 years before Christ; that Tche-kiang, inhabited by barbarous tribes, under the dominon of the Yue and Tsoo, was brought under the Chinese princes only about the same period; that Fo-kien, separated from the Chinese dominions by the kingdom of Oo, was annexed to the empire only about 200 years before Christ; that Quang-tong, inhabited by the Southern Yue, was partly subdued 214 years before Christ; but was only gradually civilized by the intercourse of the Chinese, and was finally subjugated in the year before Christ 109. The empire of China, in the earlier ages of its existence, if indeed it existed so early, must have been composed only of a few civilized clans, who lived in the midst of barbarians, and who changed their place of residence as circumstances required. This point is sufficiently established by such events as the following, recorded in the Chinese histories: namely, that in the year 1401 before Christ (1500 years after the pretended commencement of the monarchy), the Emperor Poen-keng emigrated with all his subjects to a new settlement, and assigned the example of his ancestors in vindication of the measure; that, in 1122, the empire was conquered by Voo-vang at the head of the Tcheoo, a people whom one of their succeeding sovereigns affirmed to be far from numerous; that the different tributary kingdoms, subdued by the founder of that dynasty, soon ceased to acknowledge the authority of his successors, and that at length the most powerful of them, the Tsin, introduced a new race of sovereigns 255 years before Christ; that the fourth emperor of this new dynasty, viz. Shie hoang-tee, was the first who effectually reduced these independent princes, and thus became sole master of the empire; but found such a variety of usages among these constituent parts of his dominions, that he could devise no better expedient for removing all traces of their former disunion, and compelling them to live under the same laws, than to cause all their historical records to be destroyed in the year 213 before Christ. The Chinese empire, now united for the first time, did not continue long under one head, but was soon dismembered into distinct sovereignties, till it was again established by Kao-tee, the founder of the Han dynasty, 200 years before Christ. About 220 years after the Christian era, it was again divided into three kingdoms; that of the Han, in the provinces of Se-tchuen and Shen-see; that of the Oey, in the northern part of China; and that of the Oo, in the southern regions. These three kingdoms and the reigning families were again annihilated by Voo-tee, who founded the dynasty of the western Tsin A. D. 265; while Yuen-ty, in like manner, established that of the eastern Tsin A. D. 317; but neither of these princes were long in possession of all China, and several provinces revolted during their respective reigns. After the destruction of their dynasty, A. D. 420, the whole country was thrown into a state of confusion, which gave rise to two empires, the northern and the southern. The empire of the north was almost constantly occupied by the Oey or Tartars named Topa, of whom the Yuen-Oey (or first Oey) reigned in Shan-see and Honan from A. D. 386 to 534; the Tong-Oey (or eastern Oey) reigned in Honan from A. D. 534 to 550, when they were displaced by the family of Pe-tsee, who held the throne till A. D. 578; and the Sie-Oey (or western Oey) reigned in Shen-see from A. D. 585 to 556, when they were displaced by the Heoo-tcheoo (or later Tcheoo), who prevailed till A. D. 581. The empire of the south was held from A. D. 420 to A. D. 479, by the dynasty of Song, which was followed in 479 by that of Tsee; in 502 by that of Leang; and in 557 by that of Tchin. In 581 the two empires were united by Ven-tee, founder of the Soo-ee dynasty, which was displaced in 618 by that of Tang; during the latter end of whose government, the empire was agitated by new troubles, desolated by the Tartars, named Kee-tan, and divided into so many independent sovereignties, that it was reduced within a very narrow compass, under the Heoo-oo-tay (or five later dynasties): the Heoo-lang in 907, the Heoo-tang in 923, the Heoo-tsin in 936, the Heoo-han in 947, and the Heoo-tcheoo in 951. These commotions and divisions were once more terminated in 960 by Tay-tsoo, founder of the dynasty of Song; but the two Tartar nations of Kee-tan and Kin, or Niu-tche, and the prince of Hia, still retained possession of the northern parts of China. In 1127, the Kin having destroyed the Kee-tan, the Song were obliged to remove the seat of their empire to a greater distance from these formidable neighbours, and resided in the province of Tche-kiang, till they called in the Yuen or Moguls, called by the Chinese Mong-koo, to assist them against the Kin in 1235, and were themselves overthrown by those allies in 1260, when Kublay-Khan, a descendant of the renowned Genghis-khan, became absolute sovereign of all China. Since the establishment of the Mogul dynasty, the empire has never been again divided; but has experienced two great revolutions, at the accession of the Chinese dynasty of Ming in 1368, and of the Mantchoo Tartars in 1644; and has scarcely, in any reign, been entirely free from revolts, wars, and domestic seditions. The empire of China, in short, instead of having existed as a great and united nation 3000 years before Christ, was never formed into one state till the year before Christ 220; but, being soon again dismembered, and only transiently united under successive sovereigns, has composed one sole and undivided monarchy only since the year of Christ 1279. Instead, therefore, of being regarded as a privileged country, governed from time immemorial by the same constitution, exempt from foreign conquest and intestine commotions; the only peculiarity which it possesses, in comparison with the other empires which have disappeared from the earth, is this, that, owing perhaps to its peninsular situation, at the extremity of the habitable world, and its consequent exemption from the sweep of those conquering nations, who changed the people whom they overthrew, it has preserved its manners and usages in a great measure unaltered, amidst the various revolutions and subjugations, which it has experienced.

Government.

Emperor.

The government of China bears a strong resemblance to what has been called the Patriarchal form, from which it is supposed to have originated. The emperor possesses the most unlimited authority, and can issue new laws or abrogate the old at his pleasure. He is the undisputed master of the lives of his subjects; and no sentence of death can be executed without his consent. To his revision, in like manner, every verdict in civil suits is subject, and has no force till it receive his confirmation. All his own sentences are executed without delay; and all his edicts acknowledged throughout the empire, as if they were the mandates of the Deity. He is the source of all power in his dominions; dispenses honours and offices at his will; and appoints or dismisses the mandarins of every class without controul. The princes of the blood alone, or those who bear that title, cannot be degraded or punished without a trial; but, as the sovereign has the power of nominating the judges, he always possesses the means of disposing of the life or liberty of the highest personages, who have incurred his displeasure. He has even the power of appointing his own successor to the throne, either from his own family, or from any class of his subjects; and should the person thus nominated, afterwards give evidence of being incapable or unworthy, the emperor can at once set him aside, and appoint another in his place. This unlimited power of the crown appears to be as ancient as the empire itself; and is regarded as one of the fundamental laws of the constitution.[*] It is still farther augmented and confirmed by the principle of filial respect towards the government, which is so carefully instilled into every one of the people from their birth, which arises almost to adoration, and which represents all dis-

---

[*] Some degree of check upon this absoluse power of the emperor, is supposed to be provided—

1. In the ceremony of bringing offerings to deceased ancestors; on which occasion, the emperor, however implicitly obeyed during

Government.

obedience to the commands of the monarch as an unpardonable crime.

Council.

The government is composed of the emperor's council, and of the great public tribunals. The emperor's council is composed of the ministers of state taken from the Colao, or first order of mandarins, of the presidents of the supreme tribunals, of their assessors and secretaries; but is never assembled unless upon affairs of the greatest importance; and, in general cases, every thing is directed by what is called the inner court, or private council of the emperor. There are six superior tribunals at Pekin, distinguished by the general name of Leoo-poo.

Tribunals.

Lii-poo, or *tribunal of appointments to office*, supplies mandarins wherever they are required, watches over their conduct, and keeps a journal of their transactions, to be submitted to the emperor's inspection, that he may dispense promotion or punishment, according to the merits of every individual. This court is subdivided into four subordinate tribunals, the first of which selects those persons, who are supposed best qualified for supplying the offices under government, the second examines the conduct of the acting mandarins; the third affixes the seals to public acts, assigns to every mandarin the seal of his office and dignity, and inspects the seals of the different dispatches addressed to the court; and the fourth inquires into the merit of the princes of the blood, and other grandees.

2. Ho-poo, a name which signifies grand treasurer, is *the court of finance*, and has the superintendance of the whole revenues of the empire, of the emperor's treasures, domains, and expences, of pensions, salaries, and presents, of the public magazines, customs, and coining of money. It has fourteeen courts, dispersed through the empire, subservient to its numerous objects, and assisting in its immense labour.

3. Lee-poo, or *court of ceremonies*, protects the ancient customs and religious rites; directs the repairs of temples, and the conduct of the different sects; inspects the progress of the sciences, the examinations, and schools; receives, lodges, and dismisses foreign embassies, and regulates all those points of etiquette, which form so essential a part of the Chinese government. It has four subordinate tribunals engaged in its assistance.

4. Ping-poo, or *tribunal of arms*, has jurisdiction over the whole military concerns of the empire, fortresses, arsenals, manufactories of arms, the examination and appointment of officers; and yet it is composed entirely, as well as the four tribunals in its service, of civil mandarins.

5. Hong-poo, or *tribunal of justice*, directs every thing relating to the detection and punishment of crimes; and has fourteen tribunals under its inspection, and employed in its service.

6. Kong-poo, or *the tribunal of public works*, has the care of the palaces, public halls, monuments, temples, canals, bridges, high ways, mines, manufactories, and every thing relating to foreign and inland navigation. It has four inferior courts employed in expediting its labours.

Each of these six supreme tribunals has two presidents, one of whom must be a Tartar by birth; and 24 counsellors or assessors, one half of whom are Tartars, and the other half Chinese. In order to check these various tribunals, it is enacted, that none of them shall have absolute authority, even in its own department, and its decisions can have no effect, without the concurrence of the other courts.

Next to these six tribunals is that of the princes, which is named Tsong-gin-foo, and which regulates every thing relating to the princes of the blood; keeps a register of all the children of the imperial family, with their future honours and appointments, as they are bestowed in the course of their lives, judges of their conduct, and subjects them to punishment; and presides likewise over the eunuchs, slaves, and officers of the palace.

Censors.

There is also a very important tribunal, called Too-tche-yuen, or *tribunal of public censors*, who have the inspection of the whole nation, of the emperor himself, of the supreme tribunals, of the different orders of mandarins, and of every class of citizens. Along with the chiefs of the several tribunals, they have the privilege of addressing remonstrances to the emperor himself; but it would be a capital offence in any of them to fail in shewing due respect to the person of the sovereign; and even the emperor's forgiveness could not save him from the vengeance of the laws. This tribunal sends an inspector general, called Ko-tao, to each of the six supreme tribunals, who take no part in the deliberations of these courts, but merely observes all that passes; and, without even communicating with his colleagues, renders an account in secret to the emperor of all that he has noticed. The same tribunal likewise sends visitors, every three years, to each of the provinces; and these officers, as soon as they reach their respective destinations, are superior to the governors and mandarins, whose administrations they inspect, but whose oppressions they seldom denounce, unless when they are very flagrant and extensive. They dispatch even secret visitors through all the provinces; and their enquiries are dreaded by all classes in the state. They have the power of nominating the inspector of the imperial canal, which is one of the most lucrative offices under government; and, though all the members of this tribunal of censors are only of the seventh order of mandarins, they possess, from their office, the greatest authority, and command the utmost respect.

While it is by means of the viceroys and mandarins, that the emperor governs and reigns, it is by means of these different tribunals, that he knows and sees, as it were, every thing that is transacted throughout his immense empire. As the grandees and mandarins, in their different stations, have a right to a part of that reverence, which is due to the sovereign from whom they derive their authority; he is careful, both for his own safety and the welfare of his subjects, that these officers be prevented from abusing their power, or acquiring too much influence over the people. He, therefore, changes them regularly every three years; obliges them to present themselves before him, both when they depart for their

---

his life, is assured, that his memory will be annually brought into public view after his death, and be pronounced with reverence and affection, or loaded with contempt and execrations, according to his conduct upon the throne.

2. In the tribunal of censors, which will afterwards be described, who have the power of remonstrating against every illegal and unworthy act of the emperor. And,

3. In the historiographers of the empire, whose office it is not only to give a faithful detail of public events; but to narrate even the private actions of the emperor, to collect his sentiments, and to record his memorable sayings. These documents are all lodged in a large chest, which stands in the court of one of the supreme tribunals, and which is supposed not to be opened till after the decease of the reigning monarch, or, should any thing unfavourable to his character be inserted in it, it remains shut up till after the lapse of several generations, or even to the expiration of the existing dynasty, that then these public recorders may not be influenced in their office by either fear or flattery, of the prince or his descendants.

respective stations, and when they return; and, in order to retain a stronger hold upon their allegiance, causes their children to be educated in the imperial college of Pekin. An ancient custom of the empire also requires, that they shall become their own accusers, and make confession of their faults; but, as it may well be supposed, that they would be inclined to palliate and conceal whatever affected their character, in order that the emperor may know the truth, he dispatches the secret inspectors from the tribunal of censors; and according to the information received from them, after personal enquiry in the district of the mandarins under examination, the emperor punishes or rewards; and, that these proceedings may have their full effect for the restraint or encouragement of others, the names of those, who have been censured or approved, cashiered or promoted, are inserted in the court gazette. This absolute sovereign, in short, always vigilant, distrustful, and severe, looks into every quarter; exalts or degrades his grandees in succession; and it is upon the instability of offices, and the desire of obtaining them, that he rests his own security, and that of his dominions. The policy of the Chinese emperor is to make every thing depend upon himself; to change the persons, who are in office at his pleasure; to keep up a constant mutual jealousy among the mandarins; to take care, that no one becomes too wealthy and powerful; and to be continually dividing anew the immense riches and authority, of which he has the entire disposal.

Corruption.

This plan, however, of governing the people as a family, which is the precept of Confucius, is more beautiful in theory, than practicable in reality; and, as the sovereign is unable to see every thing with his own eye, all his superintendance and vigilance are rendered unavailing, by the want of integrity in his deputies. These imperial commissaries, whose function is so formidable, who possess the authority of the emperor, who examine the conduct of the great officers, and who have the power of accusing and deposing in their hands, seldom execute their orders with due fidelity. As soon as they arrive in a province, all the mandarins hasten to wait upon them, to anticipate their wishes, and to beg their acceptance of presents. All the mandarins, entrusted with any commission from the court, are nominated by the ministry; and, as soon as their term in office is expired, they make presents to the ministers, the princes of the blood, the presidents and assessors of the tribunals, and then sit down with the rest of their gains, in full security of no inquiry being made into their administration. All complaints must pass through the principal officers, before they can reach the emperor; and these persons are all so united in interest, that no remonstrance reaches the throne without their full consent. This love of presents has always prevailed in China among the mandarins; and all the attempts of the emperors to check the practice have proved ineffectual. The two last emperors, Yong tching and Kien-long, increased the salaries of the governors of cities and provinces, and expressly prohibited them from accepting any gift. But both the persons who wish to receive, and those who find it their interest to offer, a present, are at no loss in accomplishing their object; and a valuable commodity sold for a trifle fully answers the purpose. These governors, in order to procure the means of making the rich presents, which are necessary to preserve their places, find themselves constrained to make exactions from those who depend upon them, to commit a multitude of extortions, and to shut their eyes to the abuses of their subalterns. Thus the orders of the emperor become entirely null; and the boasted reciprocal vigilance of the mandarins, is converted into a mutual league, to secure themselves from all inquiry. It does, indeed, occasionally happen, that a guilty viceroy is thrown into prison, deprived of his office, and unjust acquisitions; but those examples only suspend the pillage for a short time; and those very disgraced mandarins are soon after admitted again to favour, and sent to other provinces to repair their fortunes. "The emperor," says M. De Guignes, "makes use of his grandees, as a sponge to suck up the riches of his subjects. When the sponge is full, he squeezes it, and sends it elsewhere to be filled anew. I repeat it: The Chinese have a wonderful love of money. They embrace with avidity every possible method of procuring it; and it is very rarely that they fail in finding an opportunity." In confirmation of this remark, the same author relates various instances of *sponging* which came within his own knowledge; of which the following may be given as a specimen: "The mandarin, of whom Lord Macartney complains in his embassy, had been viceroy of Quang-ton and Quang-see. The emperor, upon nominating him to that office, observed, 'I place you in a city where there are many European curiosities, but from which nothing is ever sent to me.' It may be presumed, that the viceroy, understanding these words, when once he had reached his province, forgot neither the emperor nor himself. The Chinese, who had occasion to ask favours of him, could not procure admission to his house, under less than a present of 15,000 or 20,000 piastres, (L. 4500); and one private individual was unable to obtain permission to see him, because all that he could afford, did not amount to 10,000 piastres, (L. 2250); but the secretaries profited by the offering, and promised to speak to their master in his favour." Another instance will show how the government is deceived in the most important matters. "The Tsong-too of Canton caused a number of gallies to be built in 1794, to pursue the pirates who infested the coasts; and he wrote to Pekin, that the preparation was completed. The emperor replied, 'your predecessor assured me that there were no longer any pirates existing, and the expence of the armament must be placed to your own account.' What happened? The gallies remained there; the Tsong-too paid as he thought proper, and the pirates are still in existence. The fact is, that the preceding viceroy had actually caused gallies to be armed; but the mandarins, instead of attacking the robbers, preferred carrying on a traffic in opium; and wrote, at their return, that the object was accomplished. I have myself seen forty heads sent from Hay-nan, as the heads of pirates: a pretty evident proof, without doubt, of the expedition having been undertaken. By no means; the greater part of these heads belonged to dead bodies dug out of their graves."

Oppression.

With the greatest possible show of paternal regard for the good of the people, they are miserably neglected in the points most essential to their welfare; and in the times of famine, while the gazettes are full of the emperor's expressions of sympathy for his children, and of the measures adopted for the relief of the distressed districts, so many delays are practised, that the calamity is generally at an end before the imperial succour arrives. Sometimes these seasons of scarcity give rise to violent commotions, when the starving multitudes not only rob and murder, but actually devour each other. Then, indeed, the severity of the government is displayed, and the supreme authorities coldly calculate the necessity of putting to death a certain number of individuals, in order to restore tranquillity. "The Chinese, in short," observes the same intelligent writer, (M. De Guignes,) to whom we have already so often referred, "are treated in a most rigorous manner; and if they do not always complain, it is because they would gain little by doing so."—"I have lived a long time," he adds, "in China. I have traversed that vast empire in all its extent. I have every where seen the strong oppress the weak, and every man, who possessed any portion of authority, employ it to harass, to burden, to crush the people."

Causes of stability.

Such is the mode, in which this government, which has been so highly extolled, and whose stability has been held up as a proof of its perfection, is found to be generally administered; and how, then, are we to account for its duration and tranquillity? It is still a matter of doubt, and sufficiently open to dispute, whether the peace and permanency of the Chinese government is to be attributed to its having been originally adapted to the genius and habits of the people, or to its having completely subdued and moulded their dispositions and manners to its views and maxims. Opposite sides of this question seem to be adopted by the most recent and intelligent writers on the subject, Mr Barrow and M. De Guignes; the former, conceiving the nature of the Chinese government to have given its present impression to the character of the subjects; while the latter rather inclines to the opinion, that the government itself has arisen out of the genius of the people themselves, and that any change in the system might be attended with fatal effects. There is, perhaps, a mutual reaction between the government and the people; and while the former may have gradually been framed according to the state and temperament of the latter, it may be supposed to have become active in its turn, and to have produced, by a long process, a degree of servility in the nation, which cannot be imagined to have otherwise existed.

Filial piety.

The basis of the whole system is, the natural and unlimited authority, which a parent is understood to possess over his offspring, as long as they live; a maxim which has been industriously inculcated for ages upon the natives of China, and which is now completely interwoven with all their earliest feelings and principles. The emperor is regarded as the common father of his people, and is accordingly invested with all that absolute dominion which a parent is considered, in that country, as necessarily possessing over his family. He is not only placed above all earthly controul, but is supposed also to be of more than mortal descent. Hence he not merely takes the title of "the Great Father," but likewise styles himself "the Son of Heaven," and "the sole Ruler of the World." He himself, too, gives the example of that submissive respect, which, as the general parent, he claims from his subjects; and, at the commencement of every new year, he prostrates himself in the presence of the empress-dowager, before he receives the prostrations of his officers and attendants. The same principle pervades all the branches of authority; and the governor of a province, a city, or any other department, is considered as the father of all, who are under his immediate jurisdiction. In practice, however, as has been shewn, this plausible theory is sadly defective; and the parental affection and care of the governor has rather the appearance of cruelty and oppression; while the filial duty of the governed is little better than fear, deceit, and disaffection. The very conduct of the monarch gives sufficient proof, that it is an artificial policy, rather than an arrangement of nature, by which he rules; for, in direct opposition to that confidence and delight, with which a father should appear in the midst of his family, it is the first and great maxim of state, that he should shew himself as rarely as possible to his people in public, and then only, when he is invested with the utmost degree of magnificence and splendour.

Equalization of honours.

Another cause of the permanency and solidity of the Chinese government, may be found in the circumstance of the first honours in the state being open to the lowest of the people; which satisfies and soothes the public mind, and induces the subjects to bear with greater patience that insolence of office and stretch of power, which they themselves, their friends, or their children, may have the prospect of exercising. The very act of choosing a magistrate from the lower class, seems to give the people a higher idea of the wisdom of government, and to satisfy them that affairs will be better managed by such persons, than by any other. They are deceived in their expectation, while they still persist in cherishing it. The more obscure that the condition of a Chinese mandarin has originally been, the more he strives to make it be forgotten, by treating with contempt such as were once his equals. He imagines, that the figure of a bird or a tiger embroidered on the front or the back of his coat, bestows every species of worth; and he continues to solicit for places, till he becomes governor of a city, governor of a province, and finally reaches the dignity of Tsong-too; when he begins to abuse the authority with which he has been entrusted, resumes all the native meanness of his original education, pillages, oppresses, and grinds the people; till the emperor, acquainted with his excesses, cashiers, banishes, and remits him to the crowd, from which he had by chance been drawn. Still, however, his very misconduct and dismissal open the way to another of the people; and they are pleased with a government, which is thus every day formed from their own body.

Subordinate causes.

The following causes have also been assigned, as perhaps contributing their share of influence to the support of the constitution. 1. The low state of civilization among the Chinese, which prevents their acquisition of enlarged views of political freedom: 2. The natural barriers of the country excluding foreign enemies, and the extreme caution of the government in admitting strangers into the empire: 3. The difficulty of making progress in the language, which keeps the body of the people in ignorance: 4. The complete religious toleration which is exercised, (with only one exception, that of Christianity,) neither prohibiting the people from embracing any sect that they choose, nor compelling them to contribute to the support of one which they dislike: and, 5. The means which are employed to inculcate sober habits, and to render individuals reserved, formal, suspicious, and unsocial, which prevents all haranguing and caballing, all conferences about political right or wrong, and all plans of opposition to the will of the government.

But, leaving all farther speculations as to the means and contrivances, by which this enormous and apparently unwieldy machine of the Chinese government is kept together, and enabled to go on, let us attend to the constituent parts, which have been thus so long and so solidly bound together.

The court.

The court, or officers of state, and other attendants upon the person of the emperor in public, are incalculably numerous, and inconceivably magnificent. The general appearance of the whole, on great occasions, all robed in the richest silks, embroidered with the most brilliant colours, and tissued with gold and silver, arranging and conducting themselves in their respective places with the utmost order, silence, and solemnity, and performing every function with as much reverence and awe, as if they were celebrating some religious mystery, is said to have altogether a very striking and imposing effect. But it is only in the aggregate, when thus assembled in public exhibition, that they have any show of dignity. In private, they are extremely insignificant; and, like mere hired actors in a spectacle, they shrink into very paltry personages, when they are not upon the stage. Every officer thus attending upon court, when his public duty is performed, retires to a sufficiently miserable and solitary cell, in the environs of the palace; takes his food alone upon a square table, crowded with bowls of rice and different stews, without table linen, or napkins, knife, fork, or spoon; but with a pair of small sticks, or quills of a porcupine, throws the food into his mouth, after the manner of the common people; and, having finished his lonely meal, generally lays himself down to sleep, without ever associating with his fellow attendants in any thing like conversation or conviviality, which would infallibly excite the strongest suspicions of the government.

Court days. Their public and pompous displays are confined to certain fixed festivals, such as the anniversary of the emperor's birth-day, the commencement of the new year, the ceremonial of holding the plough, the reception of foreign embassies, &c. It is only on such occasions, that the emperor appears in public; and even then he only shews himself within the precincts of the palace, from which the populace are entirely excluded. Of these exhibitions, the emperor's birth-day is the most splendid, as at that time all the principal officers of government, civil and military, all the Tartar princes and tributary chiefs, are expected to attend. The following description of this festival, by Lord Macartney, will convey to our readers a better idea of the splendour and ceremonies of this eastern court, than any abridged view that we could attempt to give. "The 17th of September, being the emperor's birth-day, we set out for the court at three o'clock in the morning."—"We reposed ourselves about two hours in a large saloon, at the entrance of the palace inclosure, where fruit, tea, warm milk, and other refreshments were brought to us. At last, notice was given, that the festival was going to begin; and we immediately descended into the garden, where we found all the great men and mandarins in their robes of state, drawn up before the imperial pavilion. The emperor did not show himself, but remained concealed behind a screen, from whence, I presume, he could see and enjoy the ceremonies, without inconvenience or interruption. All eyes were turned to the place where his majesty was imagined to be enthroned, and seemed to express an impatience to begin the devotions of the day. Slow solemn music, muffled drums, and deep-toned bells were heard at a distance. On a sudden the sounds ceased, and all was still. Again they were renewed, and then intermitted, with short pauses; during which, several persons passed backwards and forwards in the *proscenium*, or foreground of the tent, as if engaged in preparing some *grand coup de theatre*. At length the great band, both vocal and instrumental, struck up with all their powers of harmony; and instantly the whole court fell flat upon their faces before this invisible Nebuchadnezzar."—"The music might be considered as a sort of birth-day ode, or state anthem, the burthen of which was, 'Bow down your heads, all ye dwellers upon the earth; bow down your heads before the great Kien-long, the great Kien-long.' And then all the dwellers upon China-earth there present, except ourselves, bowed down their heads, and prostrated themselves upon the ground, at every renewal of the chorus. Indeed, in no religion, either ancient or modern, has the divinity ever been addressed, I believe, with stronger exterior marks of worship and adoration, than were this morning paid to the phantom of his Chinese majesty. Such is the mode of celebrating the emperor's anniversary festival, according to the court ritual. We saw nothing of him the whole day, nor did any of his ministers, I imagine, approach him; for they all seemed to retire at the same moment that we did."

Eunuchs of the palace. At the Tartar conquest, all the eunuchs, to the number of 6000, were deprived of all offices of trust and importance; but they are still extremely numerous about the court, chiefly as keepers of the females, and as superintendants of the gardens, buildings, and other works connected with the palaces. The *rasibus*, as they are called, who are deprived of every trace of manhood, are admitted into the interior of the palace; and their chief business is to attend upon the ladies, whom they emulate in every female art of painting the face, and studying their dress. The greatest favourite among the eunuchs waits upon the emperor, and sleeps in the same room; and the power of this person in prejudicing his master is often felt by the first officers of state. These creatures, in general, are described as addicted to all the vices which distinguish the tribe in other places; as particularly insolent, rapacious, and spiteful in the extreme; as detested and dreaded by all the court officers, and even by the princes of the blood; and as requiring to have their good will secured by frequent and costly presents.

Emperor's household. The only companions of the emperor, in his leisure hours, are the women and these eunuchs. His wives are distributed into three classes. The first class consists only of one, who has the rank of empress; the second, of two queens, and their attendants; and the third, of six queens, with their train. To these are added a hundred ladies, usually called the emperor's concubines, but forming an equally legal part of his establishment; and men of the first rank account themselves highly honoured, when their daughters are admitted into this number. Their children are all considered as branches of the imperial family; but the male issue of the first empress is generally regarded as the heir apparent to the throne, though this depends, as has been mentioned, upon the will in the emperor, who has the sole right of nominating his successor, and of choosing him out of any class or family in the empire. The daughters of the sovereign are generally given in marriage to Tartar princes and officers, and rarely to a Chinese husband. The emperor's women are doomed to reside for ever within the walls of the palace; and, after his death, they are immured for life in a separate building, called the palace of chastity.

Princes of the blood. The princes of the blood, or descendants of the imperial family, are the only persons in China who can be said to possess any portion of hereditary nobility; and even their privileges are extremely few and restricted. Those who are descended in a direct line from the reigning family, have their names and date of their birth registered in a yellow book; and have the privilege of wearing a yellow girdle; but those who are only of collateral descent, that is, from the uncles or brothers of the founder of the dynasty, have their names enrolled in a red book, and the right of wearing a red girdle. Even the princes of the blood, however, beyond the third generation, scarcely possess any distinction whatever, and gradually sink into the common mass of subjects, unless they have talents and application, to attain those offices, to which honours are attached. They have the privilege of being tried only by their peers, called the tribunal of

Want of nobles.

princes, which takes cognizance of no other rank; and they may procure exemption from any corporal punishment by a fine. Their persons, also, are in some degree rendered sacred; and should any one insult a prince of the blood, when decorated with his yellow girdle, he is punished with death; but, if the prince had omitted to wear his girdle at the time of the assault, it is then considered by them as a case only between one citizen and another. Those of them, who hold no offices which give them rank and revenue, are entitled merely to draw the full pay of a soldier in the Tartar bands; and receive a present from the emperor of 100 taels, about 30 guineas sterling, when they marry. At their death, also, the same sum is allowed to defray their funeral expences; and the emperor occasionally relieves their widows and families. Princes and princesses of the inferior classes must petition the emperor for permission to marry; but princes of the direct line may omit this form, unless when they wish to be connected with any of the Tartar families. The family of Confucius, also, is accounted noble; and his descendants in the direct line enjoy a title of honour. All those, likewise, who have held the post of a mandarin, or obtained any literary degrees, continue to be accounted noble, even after they have ceased to hold office. A title of honour may be continued in a family, as a mark of the sovereign's favour, but it confers no power, privilege, or emolument, and very soon wears out. With these exceptions, it may be said that there is no hereditary rank in China. All dignities are merely personal, and attached to the holding of some office. The sons of the highest mandarins derive no authority or title from the rank of their father; and, if they have not the requisite talents and acquirements to procure office for themselves, they fall back into the common mass. As the possessions of their father, also, according to the laws of the empire, are equally divided among all his sons, the riches of the greatest families diminish in proportion to the number of heirs, and thus they soon sink down from their former splendour. Even property and character have no weight in China; but, except the morals be notoriously bad, learning and abilities, of a particular description, are the only, and almost the sure, passports to the higher offices and honours.

Court dress. The emperor and his children are clothed in robes of a bright yellow colour; while all the other branches of the royal family, and princes of the empire, wear, like the mandarins, violet-coloured garments. The emperor, his sons, and the princes of the first rank, are also distinguished, by having the figures of dragons with five claws, called Long, embroidered on their vestments; while princes of the second rank have the same dragons, with four claws; and those of the third rank, as well as the mandarins, have, instead of dragons, a species of serpent, with four claws, named Mang. The button of ceremony on the head dress of the emperor, consists of three dragons of gold, placed one above the other, with four pearls on each, one pearl between each, and one large pearl surrounding the whole. His upper robe has four circles, embroidered with the figure of a dragon, one on each shoulder, a third on his breast, and a fourth on his back. His necklace, which, in his case alone, can be composed of pearls, consists of 112 pearls, and other ornaments of rubies, sapphires, and amber. His girdle is of a bright yellow, with four circles of gold, adorned with rubies, sapphires, and pearls.

The oldest son of the emperor, named Hoang-tay-tse, has a similar button to that of the emperor, but composed of 13 instead of 16 pearls; a necklace of coral, with ornaments of sapphires; and a bright yellow girdle, with four circles of gold, adorned with azure stones and pearls.

The bonnets of the sovereign and the heir apparent have also a figure of the idol Fo surrounded with pearls.

The other sons of the emperor, called Hoang-tse, are adorned like the eldest, except that they have fewer pearls in their ornaments, and a ruby instead of the figure of Fo. The princes of the different ranks are, in like manner, distinguished, chiefly by the number of pearls in the front of their bonnets, and the colours of their necklaces.

Classes of subjects. The great body of subjects is divided into seven classes, the mandarins, the military, the literati, the bonzes, the husbandmen, the artizans, and the merchants.

Mandarins. The mandarins, whether civil or military, are the most respected; and they are chiefly taken from the three last classes. All the Chinese aspire to this rank, both as investing them with a portion of authority, and also as increasing their power of acquiring wealth. As soon as a Chinese possesses a little money, he enters into trade; and when he has become rich, he generally procures, by his wealth, the office of an inferior mandarin, that he may enjoy his possessions with greater security.

Literati. The literati are generally the candidates for places, without which, their attainments are not much respected. Their names are enrolled into the lists of the tribunal Lii-poo, which has the business of nominating mandarins, and of informing the emperor when vacancies occur.

Bonzes. The bonzes are very numerous; but their exact amount is very differently reported by writers on China. De Guignes calculates their number at one million; and observes, that they are generally in possession of lands, farms, and houses.

Husbandmen. The husbandmen are the most favoured by government; but, at the same time, the least wealthy.

Artizans. The artizans are not bound, as has been supposed, to follow the employment of their forefathers; and they generally enter into commerce, as soon as they can find the means.

Merchants. The traders are the least respectable, especially those who traffic with foreign nations.

Players and prostitutes. Players, and those who engage in the business of prostitution, are the only persons accounted directly infamous, and inadmissible as candidates for the office of a mandarin; and in the case of the former, an enactment of the Emperor Kien-long requires three generations to wipe off the stain.

The conductors of the imperial barges, who are called Kan-kia, are also of bad repute; because the persons, employed in dragging these vessels, are commonly Chinese criminals, who would otherwise have been punished with banishment.

Mandarins. The class of mandarins, with all their authority, are under considerable restrictions, to preclude the possibility of their ever becoming dangerous to the supreme power. They are changed every three years from one station to another, are incapable of holding any civil office in the province where they were born, and cannot be stationed nearer to it than 50 leagues, till they have attained the age of 60 years. They cannot marry in the province or city where they govern; and must all remove from their posts at the death of a father, mother, grandfather, or grandmother. When a mandarin obtains a superior office in a province, where one of his relations is employed, the latter is obliged to inform the tribunals at Pekin, who remove him to another place. The father, the son, the uncle, and the grandson, cannot be united in the same tribunal. If the perpetrator of a robbery or murder cannot be discovered, the mandarin of the district where the crime was committed is deprived of his office. A mandarin cannot be brought to justice as long as he is invested with authority, because he then represents the emperor; but he must be cashiered, before he can be subjected to trial and punishment. A mandarin has full power in his district; but they are all subject to the authority of those who occupy a higher degree, and the superior orders are responsible for the conduct of the inferior. Both civil and military mandarins are payed from the revenues of the province, in the different parts of which they are employed; but their salaries are barely competent to defray the expences of their office, which is one cause of their general inclination to pillage the people. The highest does not amount to 1000 crowns; but, in spite of all the checks which the laws have placed upon their conduct, they easily find means not only to supply their wants, but also to acquire wealth. It is so rare to see one of them leave his employment without having become rich, that a disinterested mandarin is regarded by the Chinese as a phenomenon; and it is a common proverb in the country, that the emperor lets loose just as many wolves and robbers as he creates mandarins. Notwithstanding this general opinion of their character, and the circumstance of their being all taken chiefly from the lower classes of citizens, the people obey them with great reverence. They are saluted with the appellations of Lao-ye, or lord; Ta-lao-ye, or great lord; Ta-gin, or great man. Every one, who is not himself invested with an office, or honoured by a literary degree, must bend the knee when he addresses a mandarin; and every person, who meets him on the road, must stand with his head erect, and his arms by his side, till he has passed. This awe and servility is kept up by the great show which they attempt to make, and by the severe punishments which would be inflicted, upon the least symptom of disrespect. They never appear in their districts without a considerable retinue, composed of all who belong to their tribunal, consisting frequently of more than 100 persons. The procession is opened by two men, armed with long flat bamboos, for inflicting the bastonade, who call out at intervals to intimate the approach of the mandarin, and who are followed by two drummers, beating on large copper kettles. After them walks a company of executioners, provided with chains, whips, and sabres; and next the bearers of parasols, standards, and other insignia of authority. A few soldiers on horseback then appear, preceding the palanquin of the magistrate, which is borne by four men, and surrounded by his principal domestics. A few more soldiers, mingled with persons carrying various articles, which are required in the service of the great men, terminate the train. But all this apparent pomp, which consists chiefly in the number of attendants, discovers, upon a nearer inspection, very little magnificence, neatness, order, or wealth. Excepting those, who are stationed nearest to the person of the mandarin, the persons who compose the retinue are poorly clothed; the parasols are often in tatters; and whenever the mandarin leaves his palanquin, the cavaliers mix with the lowest soldiers, executioners, and other menials, and may all be seen together upon the ground engaged at different games.

Dress of the mandarins.

All the mandarins wear robes of a violet colour, and are alone entitled to use golden embroidery. Their different orders and degrees are minutely distinguished by particular kinds of dress; and their wives also are habited in a manner conformable to the rank of their husbands. They are characterised at one glance by the figure upon the front and back of their robe, by the colour and form of the girdle, and by the button upon the top of their bonnets, of which they have two kinds, the bonnet of ceremony, and one for ordinary use. There is a difference also between their winter and summer dress: the former of which, ornamented with furs, is put on about the middle of October, and laid aside about the middle of April. The chief mandarins are distinguished farther by having eight bearers of their palanquins, while the inferior orders have only four, and private persons never more than two.

There are nine orders of mandarins, who are distinguished, besides other less prominent marks, as follows:—

1. By a ruby of *transparent red* on their bonnet; by the figure of a Ho, or *pelican*, on the front and back of their robe; and by four stones of *agate*, with rubies on their girdle. The military officers of the same order, having the same decorations, but instead of the pelican, have the figure of Ky-lin, *a fabulous animal.*

2. By a ruby of *opaque red*, the figure of a Kin-kee, or *golden hen*, and four wrought squares of gold, with rubies on the girdle: The military officers of the same order, have the figure of a Sie, or *lion.*

3. By a sapphire of *transparent blue*, the figure of a Kong-tsio, or *peacock*, and four squares wrought with gold on the girdle: The military officers of the same order have the figure of a Pao, or *panther, with round spots.*

4. By a stone of *opaque blue*, the figure of a Yen, or *crane*, and four squares of wrought gold, with a silver button on the girdle: The military officers of the same order have the figure of a Hoo, or *tiger.*

5. By a rock crystal of *transparent white*, the figure of a Pe-hien, *white-pheasant*, and four squares of plain gold, with a silver button on the girdle: The military officers of the same order have the figure of a Hiong, *bear.*

6. By a marine shell of *opaque white*, the figure of a Lu-su, *stork*, and four round plates of shell, with a button of silver on the girdle: The military officers of the same order have the figure of a Pien, or *small tiger.*

7. By a *small crystal* and button of plain gold, the figure of a Kee-she, *partridge*, and four round plates of silver upon the girdle: The military officers of the same order have the figure of a See, *rhinoceros.*

8. By a button *of wrought gold*, surmounted by another of the same kind, the figure of a Ngan-shun, a *quail*, and four plates of rams-horn, with a silver button upon the girdle: The military officers of the same order, have the figure of the 7th order, the See, or *rhinoceros.*

9. By a button *of wrought gold*, surmounted by another of silver, the figure of a Tsio, or *sparrow*, and four plates of black horn, with a silver button upon the girdle: The military officers of the same order, have the figure of a Hay-ma, *sea-horse.*

Next to the mandarins, the persons who have obtained degrees in the civil or military examinations, and who are the candidates for vacancies in these orders, have also a distinguishing mark according to their progress, and which consists chiefly in a button of wrought gold, a button of wrought silver, or a button of plain silver.

Civil mandarins.

Of the civil mandarins, the chief officers, who govern the empire, are the

1. Ttsong-too, whose jurisdiction extends over one or two provinces; and of whom there are reckoned only eleven in the empire.

2. Foo-yuen, or governor of a province.

3. Poo-tching-sse, or chief treasurer, and civil judge.

4. Ho-poo, or collector of the customs, an office peculiar to the two provinces of Quang-ton and Fokien.

These four mandarins are taken always from the members of some of the supreme tribunals at Pekin.

5. Ngan-sha-sse, chief criminal judge.

6. Tao-ye, or intendant of two cities of the first order.

7. Tching-tchoo-kao, or president of examinations, who is always sent from Pekin.

8. Hio-yuen, or inspector of schools, also sent from Pekin.

9. Yen-yuen, or intendant of the salt-works.

10. Y-tchooen-tao, or intendant of ports, the shipping, and boats.

11. Pin-pee-tao, or inspector of troops.

12. Tun-tiao, or intendant of the high-ways.

13. Ho-tao, or inspector of rivers.

14. Hay-tao, or inspector of the sea-coasts.

15. Tchee-foo, governor of a city of the first order.

16. Tchee-tcheoo, governor of a city of the second order.

17. Tchee-hien, a governor of a city of the third order.

18. Eul-foo, or sub-governor.

19. Eul-ya, assessors or assistants to the governors.

20. Nan-hay, or head of police, with his assistants.

21. Shooy-ko-tse, receiver of the duties from merchants shops.

22. Sse-yu, keeper of prisons.

23. Shooy-ta-she, chief of the custom-house.

24. Koo-ta-she, inspector of the magazines.

25. Y-tcheng, inspector of the posts in the city.

26. Hio-tcheng, inspector of the schools in a city.

Each of these mandarins has a council or tribunal, under his command, called Ya-men, or assistants. The smaller towns and villages have, in like manner, their respective magistrates; and the whole number of civil mandarins in the empire are calculated by different writers at different amounts, of which the average is about 10,000.

Military mandarins.

There are at Pekin five military tribunals, called Oofoo, which comprehend the five classes, into which all the military mandarins are arranged.

1. Heoo-foo, or rear-guard.

2. Tso-foo, or left-wing.

3. Yeoo-foo, or right-wing.

4. Tchong-foo, or centre-corps.

5. Tsien-foo, or advanced guard.

Each of these classes have at their head a president, and two assessors or assistants, taken always from the most distinguished officers; and they are all subject to a supreme tribunal named Jong-tching-foo, whose president is one of the highest grandees of the empire, and to whom are attached a civil mandarin as colleague, and two assistants. This tribunal watches over all the officers and soldiers of the court, but, in matters of importance, is itself subject to the civil tribunal called Ping-poo.

The names of the Tartar military mandarins, and the number of men under the immediate command of each, are,

Tsiang-kiun, equivalent to a general; 3000.
Too-tong, to a lieutenant-general; 1000.
Koo-shan, to colonels.
Tsang-ling, to lieutenant-colonels of cavalry.
Fang-yu, to captains.
Hiao-kee-kiao, to lieutenants.

Chinese military mandarins.

Tee-too, commander of the troops of a province; 4000.
Tchong-kiun, his lieutenant-general, whose station is in the centre of the army; 3000.
Tsong-ping, generals; 3000.
Foo-tsiang, marshals of the camp.
Tsang-tsiang, commander of brigades.
Yeoo-kee, colonels.
Sheoo-pey, lieutenant-colonels.
Tsien-tsong, captains.
Pa-tsong, lieutenants.
Pe-tsong, centurions, or commanders of a hundred men.

The number of military mandarins, including the centurions, is between fifteen and twenty thousand; but they are greatly inferior in influence to the civil officers.

RELIGION.

It is scarcely possible to give a distinct account of the religion of China, and to class its numerous superstitions under appropriate heads. It is indeed pretended by some writers (Father Amiot) on the subject, that the ancient religious system of the Chinese has continued unchanged amidst all the corruptions, which have been grafted upon it during many successive ages; that this system is found to agree, in its most essential parts, with that of the Israelites, before the giving of the law by Moses; and that it may be traced back, by means of regular traditions, even to the renewal of the human race, by the grandsons of Noah. It is affirmed, on the contrary, by an intelligent traveller of our own country, (Mr Barrow) that the primitive religion of China no longer exists, or exists only in a most corrupted state; that there is at present no national, nor scarcely any state, religion, in the empire; and that the articles of faith are as various as the modes of worship. All that we can attempt, therefore, amidst these discordant opinions, is to present our readers with a short view, first of the principal religious systems, which have been introduced into China at different periods, as far as can be ascertained from their own historical records; and next, of their present religious observances, as far as these have been described by later travellers in that country.

All accounts of the religious opinions and ceremonies of the Chinese, previous to the time of Confucius, are mixed with fable, and full of uncertainty. Indeed, as their best existing historical documents must be regarded as his productions, and are at least ascribed chiefly to his pen, by the Chinese themselves, none of the allusions to religious practices, which are to be found in the earliest periods of their history, can be considered as resting upon any authority, more ancient than his. But as the Chinese affirm the greater portion of their canonical book Shoo-king to have been composed, long before the age of Confucius, and to have only been restored by his labours; we may proceed upon this idea, and consider the tenets expressed in this work, as the ancient religion of China.

Primitive religion.

In this view of the subject, their primitive creed seems to have contained the general doctrines of theism with regard to the Supreme Being, whom they worshipped under various names, such as Tien or Kien, *heaven*, Shang-tien, *supreme heaven*, Shang-tee, *supreme Lord*, and Hoan-shang-tee, *sovereign and supreme Lord*. This Supreme Being they regarded as possessed of all natural and moral perfections, as exercising a minute and judicial providence over mankind, as rewarding virtue and punishing vice, even in this life, as sending calamities to warn and reform the offender, and as ready to relent, and pardon him upon his repentance. The first worship instituted in honour of the Shang-tee, consisted in prayers accompanied with sacrifices or gifts, offered upon some natural eminence, or artificial mount, or merely in the open fields, upon an altar called *tan*, composed of a round heap of earth, or of a quantity of stones thrown together in a round form. At a very early period, however, of their history, we find them associating with the Shang-tee, or Supreme Being, a multitude of tutelary spirits as objects of worship, under the name of Shin, or Kooey-shin. Around the Tan, or supreme altar, was drawn a double fence called Kiao, constructed with turf and branches of trees; and in the space, which was thus inclosed, two smaller altars were erected, one on each side of the Tan; and, upon these, immediately after the sacrifice offered to the Tien, they sacrificed also to the Shin, that is, to the superior spirits of every rank, and to their virtuous deceased ancestors, imploring their protection and mediation with the Shang-tee. Their code of morals, at this period, was comprehended in two virtues, Jin and Y; the first of which expressed piety to God and to parents, or good will to mankind in general; and the second signified equity or justice. The sovereign alone, who was considered as the high priest of the empire, had the privilege of sacrificing to the Tien; but any other person might supply his place in making offerings to the Shin. In the earlier ages of the empire, when its boundaries were not very extensive, one mountain was sufficient for the performance of these rites; but, as its territories increased, four principal mountains, situated in the extremities of the empire, and corresponding with the four quarters of the globe, were consecrated by the Emperor Hoang-tee, as the scenes of religious worship to the nation; and, in the course of every year, the sovereign went to these sacred places successively to offer worship, to shew himself to his people, to inform himself of their requests, to reform abuses, and to establish good order. It was afterwards more particularly ordained by the emperor Shun, that a solemn sacrifice should be offered at the second moon, or vernal equinox, on the eastern mountain, to implore a blessing on the seed cast into the earth; at the fifth moon, or summer solstice, on the southern mountain, to pray for a genial warmth upon the vegetating soil; at the eighth moon, or autumnal equinox, on the western mountain, for the preservation of the ripening crops; and at the 12th moon, or winter solstice, on the northern mountain, to give thanks for the blessings received during the preceding year, and to supplicate a continuance of the same favour through the approaching season. A fifth mountain was afterwards added in the middle of the empire; and the whole were in succeeding times called the five Yo, or mountains of sacrifice. These regular journeys, however, on the part of the emperor, having been found to be attended with numerous difficulties and inconveniences, an edifice was erected in the neighbourhood of the palace, which represented the Tan, the Kiao, and the hall of ancestors, or space between the fences of the Kiao, as a stationary and universal Yo; and here the emperor offered the appointed sacrifices, when it would not have been practicable or prudent for him to remove from his capital. This edifice contained five separate apartments, with four bare walls in each, without paintings or ornament, and with nothing but windows to admit the light; and it received from succeeding dynasties various additions, with new appellations. Under the dynasty of Hia, 2205 before Christ, it was named She-shee, or the house of generations and ages; and was rebuilt by the Shang 1766 years before Christ, with the appellation of Tchoo-oo, or the renewed temple. A similar structure was raised by the Tcheoo, and named Ming-tang, or the temple of light, 1122 years before Christ; but future dynasties, desirous to surpass their predecessors, divided the word ming or light into its component characters, Ge the sun, and Yue the moon; and built two temples, one to each of these luminaries. Hence arose a multitude of superstitions; and the wind, the rain, the thunder, diseases, &c. were all, in like manner, personified, and addressed as divinities, while warriors, emperors, and illustrious men, became demi-gods. The people forgot the simple worship of the Shang-tee, and embraced every new invention of idolatry with the utmost avidity.

Sect of the Tao-tse.

The most ancient of the religious sects, which have, at different periods, engrafted their superstitions upon the primitive theological system of China, is that of the Tao-tse, or sons of immortals, which was founded by a philosopher named Lao-kiun, or Lao-tse, who was born in the province of Honan, about 600 years before Christ, and concerning whose birth a multitude of strange stories are circulated among his countrymen. His mother, it is believed, suddenly conceived in a retired place, by the united influence of heaven and earth; continued in a state of pregnancy for the space of 80 years; and at length, under the shadow of a plum-tree, brought forth a son, with hair and eye-brows perfectly white. From these circumstances he received the names of Ly-eul, or *plum-tree-ear*, and of Lao-tse, or gray-haired child. Independent of these absurdities, Lao-tse is said to have held the office of librarian to one of the emperors of the dynasty of Tcheoo, by whom he was afterwards raised to the rank of an inferior mandarin. From his situation in the midst of books, he became addicted to literary pursuits, and acquired a profound knowledge of the ancient history and usages of his country; but, disgusted by the degeneracy of the times in which he lived, he travelled into the kingdom of Thibet, where he imbibed the tenets of the priests of Lama, and wrote a book entitled Tao-te-king, or the book of the power of Tao, composed of 5748 characters, and consisting of detached thoughts and maxims, expressed in a very concise and unintelligible style. According to his doctrine, the Tao is the principle of heaven and earth, the source of all that exists, a highly intelligent, but, at the same time, utterly incomprehensible being. He who desires to be united to the Tao is named Shing, and is the only wise man; and to attain this character, he is required to be free from the influence of every passion, to reject riches and dignities, to employ himself in no kind of sublunary pursuit, to keep silence, to censure nothing that exists, to live as if he lived not, and to cherish compassion to his fellow creatures.

His followers, named Tao-tse, therefore, place the supreme duty and felicity of man in a state of perfect tranquillity, recommending the suppression of all violent desires and passions, the utmost moderation in every pursuit or enjoyment, and an utter indifference with regard to the past, the present, or the future. But as this apathy, or tranquillity, which their master inculcated, and which they laboured to attain, was necessarily disturbed by the prospect of death, they adopted a notion, which they are supposed to have derived from the idea of the soul of the Lama passing into the person of his successor, and imagined, that a liquor might be compounded from the three kingdoms of nature, which would possess the virtue of renovating the vigour of the human body, and of rendering it finally immortal. In pursuit of this beverage of immortality, they addicted themselves to the study of alchymy, which they mixed up with various magical practices, tricks of divination, and other superstitious absurdities. The hope of avoiding death drew to them a multitude of followers, especially among the more opulent classes; and several of the emperors abandoned themselves entirely to their opinions and practices.

Their tenets made the most rapid progress throughout the empire; and the court was filled with the teachers of the system, who received the title of Tien-tse, or "celestial doctors," while their chief was honoured with the dignity of a grand mandarin, which his successors are said still to retain, residing in a splendid palace in the province of Kiang-see, to which multitudes of worshippers continually resort. These draughts of immortality, sought after with so much avidity, were not unfrequently rendered instrumental in cutting off the sovereigns and grandees of the empire, by administering a poisonous dose in their place; and, even in their most genuine state, they are supposed to have, in many instances, brought on a premature decease. This beverage of life, which is still held in great request, especially among the higher classes of the Chinese, is understood to be a compound of opium, and other stimulating drugs, which excite the system and exhilarate the spirits for a moment; but, by the frequent repetition of the dose, which the languor by which it is succeeded renders necessary, the constitution is at length exhausted, and the period of life is thus abbreviated, rather than prolonged, by the pernicious superstition.

This sect became particularly powerful under the dynasty of Song; and one of the emperors of that race carried his superstitious reverence for a celebrated teacher among them to such a length, as to command him to be worshipped under the name of Shang-tee, which had hitherto been appropriated to the Supreme Being. The sages of the nation were so greatly shocked by this act of impiety, that they predicted the ruin of that dynasty as fast approaching; and the wiser part of the learned men frequently presented strong remonstrances to different emperors against the patronage which was bestowed upon these deceivers; but the sect of the Tao-tse continued to increase in power and numbers, under the protection of princes, the countenance of the great, and the credulity of the people; and has preserved its extensive influence even to this day, in spite even of all the attempts of the celebrated Confucius to introduce more enlightened doctrines.

Sect of Confucius.

Confucius or Kong-foo-tse was born about 550 years before Christ, and is regarded by the Chinese as the chief of their wise men, and as the author of their whole civil constitution. He endeavoured to restore the ancient system, and to improve the conduct of his countrymen, by exhorting them to obey the commands of heaven, to love their neighbours, and to restrain their passions. Some of his philosophical principles are, that out of nothing there cannot any thing be produced; that material bodies must have existed from all eternity; that the cause or principle of things must have had a co-existence with the things themselves; that this cause, therefore, must also be eternal, infinite, and indestructible; and that the central point of influence, from which this cause chiefly acts, is the blue firmament, (tien) whence its emanations are spread over the universe; but neither he nor his disciples ascribe to the deity any personal existence, or represent the first cause under any distinct image; while the sun, moon, stars, and elements, are considered also as composing the firmament, or tien, as the immediate agents of the deity, and as the productive powers in creation. The universe, in short, according to this philosopher, is one animated system, made up of one material substance, and of one spiritual being, of which every living thing is an emanation, and to which, when separated by death from its particular material part, every living thing again returns; hence the term death is never used by his followers, but they say of a person, at his decease, that he has returned to his family. Thus he taught, that the human body is composed of two principles, the one light, invisible, and ascending, the other gross, palpable, and descending; that the separation of these two principles causes the death of human beings; and that, at this period, the light and spiritual part ascends into the air, while the gross and corporeal matter sinks into the earth. He taught, farther, that the spirits of those, who had performed their duty in life, were permitted to revisit their ancient habitations, and such places as might be appointed for receiving the homage of their descendants; that they have the power of conferring benefits upon their posterity; that it was thus the indispensable duty of every man to perform the sacred rites to the memory of his ancestors; and that, whosoever neglected this duty, would be punished, after death, by his spirit being rendered incapable of visiting the hall of ancestors, and receiving the homage of his descendants. Besides the performance of these sacred rites to the memory of ancestors, the principal religious worship which he required, was, that the prince, in the name of his people, should present offerings to the tien, particularly at the two equinoxes, for the purpose of obtaining a propitious seed-time and a plentiful harvest; but, at the same time, that the deity is always best satisfied when men perform the moral duties of life, which he comprised chiefly in these two, viz. filial piety towards parents, and unreserved obedience to the will of the emperor. With these tenets was naturally connected a belief of good and evil genii, and of tutelary spirits presiding over families, towns, mountains, and other places; and while the system of Confucius was little better than atheism in the mind of the philosopher, it became a source of gross idolatry among the people, who could not comprehend the more refined notions, but, needing some visible object upon which to fix their attention, represented the tutelary spirits by images, and worshipped them by sacrifices. Confucius himself was much addicted to a species of divination or fortune-telling, and says expressly in one of his works, that the wise man ought to know future events before they happen, and that this may be done by means of lots. His tenets, in short, instead of overcoming the old errors, gave rise to new superstitions; and the chief difference between the proper followers of Confucius and those of Lao-tse, is this, that the former inculcate the duty of living among men, and endeavouring to improve them; while the latter avoid every kind of society and occupation, and lead a frugal retired life, as their only felicity.

Sect of F

During the reign of the Emperor Ming-tee, of the Han dynasty, a new superstition was introduced into China, whose influence is perhaps still more extensive and pernicious in that country, than any of those by which it was preceded. One of the Tao-tse doctors had promised to a brother of the emperor's, that he would open to him a communication with the spirits; and this superstitious prince having heard of a spirit in Tien-tso, or Hindostan, named Fo, or Foe, prevailed upon the emperor, by his importunities, to send an embassy for this foreign divinity. When the officer, who was entrusted with this mission, arrived at the place of his destination, he found only two Sha-men, or priests of Fo, whom he carried to China, with some of their canonical books, and several images of the idol painted on linen. The followers of Fo describe him as the son of a prince of one of the kingdoms of India, near the line; and affirm, that as soon as he was born he stood upright, walked seven steps without assistance, and, pointing to the heavens with one hand, and to the earth with the other, cried aloud, "in the heavens and the earth there is no one but myself who deserves to be honoured." At the age of seventeen, he married three wives, by one of whom he had a son, named by the Chinese Mo-heoo-lo; but at the age of nineteen he abandoned his house and family, with all the cares of life, and committed himself to the care of four philosophers, with whom he retired to a vast desert. Being filled with the divinity at the age of thirty, he was metamorphosed into the Fo, or Pagod, as the Indians term it, and immediately thought of establishing his doctrines by miracles, which attracted numerous disciples, and spread his fame over every part of India. When he had attained his seventy-ninth year, and perceived from his infirmities that his borrowed divinity could not exempt him from mortality, he is said to have called his disciples together, and to have declared to them, that hitherto he had spoken to them by figurative expressions, but that now he would discover his real sentiments, and unveil the whole mystery of his wisdom, namely, that there is no other principle of things but a vacuum, or nothing; that from this nothing all things at first sprung; that to nothing they shall again return; and that thus end all our hopes and fears at once. After his decease, a multitude of fables were propagated concerning him by his followers, such as, that he was still alive, and had been born 8000 times, appearing successively under the figure of an ape, a lion, a dragon, an elephant, &c. His last words excited much dissension among his disciples, some of them resolving to adhere to his original tenets, others adopting his concluding atheistical view of things, and a third class attempting to reconcile both systems together, by making a distinction between the external and internal doctrine. The internal doctrine, to which the disciples of the idol are exhorted to aspire, is a system of the most absurd atheism; of which some of the principal tenets are, that nothing is the beginning and the end of all things; that all beings are the same, differing only in figure and qualities; that the supreme happiness of man consists in acquiring a resemblance to this principle of nothing, in accustoming himself to do nothing, to will nothing, to feel nothing, to desire nothing; that the sum of virtue and happiness is to be found in indolence and immobility, in the cessation of bodily motion, the suspension of all mental faculties, the obliteration of all feelings and desires; that when men have attained this divine insensibility, they have nothing to do with virtue or vice, rewards or punishments, providence or immortality, no changes, transmigrations, or futurities to fear, but have ceased to exist, and become perfectly like the god Fo. The external doctrine has the greatest number of followers. It teaches a great distinction between good and evil, and a state of rewards for the good, and of punishment for the wicked after death, in places suited to the spirits of each. It acknowledges the transmigration of the soul through different bodies, till it is at length completely purified and prepared to be united to the Deity. It affirms, that the god Fo came upon this earth to expiate men's sins, and to secure them a happy regeneration in the life to come. Its practical injunctions are simply these: To pray to the god Fo, and to provide his priests with temples and other necessaries, that by their penances and supplications they may procure for his worshippers, the forgiveness of their sins; and to observe five precepts, viz. to kill no living creature—to take nothing that belongs to another—to commit no act of impurity—to utter no falsehood—and to drink no wine. The practice of these duties is enforced by threatenings of future punishment, especially of transmigration into the bodies of dogs, horses, rats, serpents, &c. In consequence of this doctrine, a multitude of idols have sprung up wherever the religion of Fo has prevailed; and temples have been erected to quadrupeds, birds, and reptiles of every description, according as the god was imagined to have occupied any of their bodies in the course of his transmigration.

Fo is supposed to have lived 500 years before the time of Pythagoras; and from his followers the Grecian sage is conjectured to have learned the doctrine of the metempsychosis, when he travelled in India. The worship of Fo was introduced into China A. D. 69; and is understood to have been originally the same as that of the Indian Buddha, from the evident coincidences between the history and worship of the two divinities. The Buddha of the Hindoos was the son of Ma-ya, and one of his names is Amita. The Fo of China was the son of Moy-a, and one of his names is Om-e-to, or, as it is pronounced in Japan, Amida. The Menshin, or guardian spirit of the door in China, is the same as the Ganesa of Hindostan; and, in both countries, his figure, or at least the character expressing his name, is painted on the door of almost every house. The Lui-shin, or spirit of thunder of the Chinese, represented under the figure of a man with the beak and talons of an eagle, is equivalent to the Vishnu of the Hindoos, who is generally figured as riding upon an eagle, or at least attended by that bird; and it is noticed as a curious circumstance, that the same reason is assigned by the Chinese for giving an eagle's face to this idol, which Pliny adduces for the consecration of that bird to Jupiter, viz. that there is no instance known of an eagle having been killed by lightning. So, Hai-vang, king of the sea, represented in China as reposing on the waves with a fish in his hand, corresponds with the Hindoo Varuna riding on a fish; and the Indian Ganga or goddess of the Ganges, has an exact counterpart in the Shing-moo or holy mother of the Chinese, which will be described in its place.

Religious persecutions.

Between the followers of Lao-tse and of Fo, which have always been the two prevailing sects in China, the greatest rivalship and enmity have constantly subsisted, which frequently extended to persecution and bloodshed. Whenever the court or principal eunuchs appeared to favour the one in preference to the other; the more powerful sect at the time commenced hostilities against its opponent. These contests, however, were confined to the priests of the two religions; and the people either remained neutral or took no active part in the quarrel, which was seldom terminated but by the levelling of monasteries to the ground, and the slaughter of some thousands of priests on both sides. Since the accession of the Tartar dynasty, no particular preference or distinction has been shewn to either of them; and indeed, except that the priests of Lama are paid and supported by the Tartar government, as a part of the imperial establishment, and that the principal Tartar officers are attached to their tenets, (separated from the absurdities grafted upon them by the Tao-tse,) the government gives no particular support to any religious sect whatever.

Sect of Shao-kang-tse.

About the year of Christ 1070, under the dynasty of the Song, several learned men applied themselves to interpret the sacred books called King; and one of them named Shao-kang-tse, distinguished by his superior erudition, became the founder of a new system. He taught first of all, that the world had a beginning and will come to an end, when it will be again produced, and again destroyed in endless succession. He fixed its duration at 129,600 years, which he divided into twelve periods, each containing 10,800 years. In the first of these, the heavens were gradually created by the motion, which the Tay-kee impressed upon matter, which had hitherto remained immoveable; in the second, the earth was produced in the same deliberate manner; in the third, men and the other living creatures began to come into existence; and so on to the eleventh period, when all things shall be destroyed, and the world shall return into the state of chaos, from which it shall not again be evolved till the end of the twelfth period. About the year 1400, the Emperor Yong lo of the Ming dynasty, commanded several learned men to combine the principles of Shao-kang tse into a system, by interpreting the books of Confucius and Meng-tse, called King. In this work they gave the name of Tay-kee (or great height) to the cause of all things, although this word is not to be found in the writings of Confucius or Meng-tse; but, from a passage in one of the commentaries of the former philosopher, they profess to derive those tenets, that Tay-kee is separated from the imperfections of nature, is an existing being, and the same with the heaven, the earth, and the five elements; that when he moves, he produces Yang, that is, subtle and active matter, such as the heavens, fire, day, that which is perfect and of the male sex; that, when he rests, he produces Yn, that is gross and motionless matter, such as the earth, the moon, darkness, that which is imperfect and of the female sex; that, by the union of these, are produced eight elements, which, by their various combinations, form the peculiar and distinguishing nature of all bodies, the vicissitudes of the universe, the fertility or barrenness of the earth, &c. From these and similar mysticisms, the partisans of Tay-kee went on in their speculations, till they ended in atheism, by excluding from the world every supernatural cause, and admitting only an inanimate virtue or energy in union with matter. In their system of morals, they adopted more rational principles; directed the wise man to make the public good the great object of his actions, and to extinguish his passions, that he may follow the light of reason; and explained the reciprocal duties of princes and subjects, of parents and children, of husband and wife.

Mixture of tenets.

None of these different systems can be said to be the prevailing creed in China; or, what is more remarkable, can be found existing pure and distinct from the rest. The greater part of the Chinese have no decided opinion whatever on the subject, and are either complete atheists, or, if they acknowledge a Supreme Being, utterly ignorant in what view he ought to be regarded; while they all combine with their peculiar sentiments the multifarious superstitions of the more popular sects. Of all these tolerated and established religious persuasions, the emperor is the supreme head; without whose permission not one of them can enjoy a single privilege or point of pre-eminence; and who can diminish or increase, at his pleasure, the number of their respective temples and priests.

The existing worship of China, then, is a confused mixture of superstitions, of which individuals receive and observe just as much as they please; and those parts of it, which the government seems to uphold, may be viewed rather as political than religious institutions. The emperors reserve to themselves the privilege of adoring the Tien, but they equally sacrifice to the spirit of the earth, the sun, or the moon, and attach themselves more or less to the notions of the Tao-tse or of Fo. While the reigning Tartar family acknowledge more particularly the faith of the Grand Lama, they nevertheless perform the established sacred rites of their predecessors, and repair to the festivals which the calendar prescribes. And, while the literati study the doctrine of the King, they are as superstitious as unbelieving, and are found with others in the temples praying to the idols.

National worship.

There is only one temple consecrated to the Tien in the whole empire, called Tien-tan, or the eminence of heaven, and is situated in the Chinese division of the city of Pekin, where the emperor offers a sacrifice at the winter solstice, consisting of oxen, hogs, goats, and sheep. The Tee-tan, or eminence of the earth, is also situated in the Chinese city, and is covered with green tiles; where the emperor, in like manner, sacrifices to the earth at the summer solstice. The Ge-tan, or temple of the sun, is on the outside of the Tartar city towards the east; and thither the emperor sends a prince every year, at the vernal equinox, to perform the rites in honour of that luminary. The Yue-tan, or temple of the moon, is also situated on the outside of the Tartar city, towards the west; and thither the emperor sends a person, in like manner, at the autumnal equinox, to perform the ceremonies in honour of the moon. These different structures have been adorned in modern times with all the magnificence of architecture; and when the emperor is about to offer sacrifice in the temple of the heaven or that of the earth, the greatest pomp and solemnity is observed. Previous to the intended ceremony, the monarch and all the grandees, who are entitled to assist, prepare themselves, during three days, by retirement, fasting, and continence. No public audiences are given, and no tribunals are open. Marriages, funerals, and entertainments of every kind are prohibited; and no person is permitted to eat either flesh or fish. On the appointed day, the sovereign appears in the utmost possible splendour, surrounded with princes and officers of state, and attended by every circumstance demonstrative of a triumph. Every thing in the temple, corresponds in magnificence with the appearance of the emperor. The utensils are all of gold, and never applied to any other purpose; while even the musical instruments are of an uncommon size, and also reserved for such solemn occasions. But while the monarch never displays greater external grandeur and state, than during these processions, he never exhibits greater personal humility and dejection than during the time of sacrifice, prostrating himself on the earth, rolling in the dust, speaking of himself to the Shang-tee in terms of the utmost abasement, and apparently assuming so much magnificence of appearance and attendance, only to testify, in a more striking manner, the infinite distance between the highest human dignity and the majesty of the supreme Being.

Ceremony of commencing the seed time.

One of the principal religious ceremonies, which the emperor performs, is that which regards the tilling of the ground, and which takes place at the vernal equinox. He prepares himself for this festival by three days solemn fasting and worshipping: and then, going forth in great pomp, takes the plough into his hand, opens the earth, and sows the first seed of the season; while the same is done in every part of the empire by his governors and viceroys as his substitutes. The grain which is gathered from the seed, thus sown by the royal husbandman, is reverently deposited in a sacred granary, and reserved for great sacrifices to the Shang tee. This ceremony may be regarded as a wise political institution for the encouragement of agriculture, as well as an act of religious worship. On the day of this observance, a cow is sacrificed in the temple of the earth, and figures of cows are carried in procession, which are afterwards broken in pieces and distributed among the people; a circumstance, which gives this ceremony some resemblance to the worship of Osiris in Egypt, from which it has not improbably been supposed to derive its origin.

Festivals.

New year.

As there is no regular day of religious rest in China, and experience proves, that certain seasons of cessation from labour are necessary for human beings, there are a number of public festivals in the course of every year, which may be considered both in the light of recreations, and of religious observances. One of the most remarkable of these takes place at the new-year; and is universally celebrated throughout the empire, at great expence. Every one endeavours to collect some money for the occasion, dresses in his best apparel, dispenses with every kind of business, and particularly provides himself with new shoes. The new-year is welcomed by firing immense quantities of crackers, with the fragments of which it is said the streets are sometimes so completely covered, that the pavement cannot be seen. The day is employed in paying visits, giving presents, and congratulating almost every one that comes in the way. Red papers are suspended around the doors, as a mean of securing good fortune through the year; and some quarters are illuminated with lanterns.

Feast of lanterns.

On the 15th day of the first moon of the year, occurs the feast of lanterns, which frequently continues for several days; and which is celebrated by suspending numbers of lanterns before the doors of the houses, and in the middle of the streets; while the more wealthy give entertainments to their friends, and exhibit shows, fireworks, &c. to the populace. Different and very trifling reasons are assigned by the Chinese for the origin of this ceremony; one of which is, that the daughter of an eminent mandarin having fallen into a river, in which she was drowned, her father and the people of the place sought her a long time in vain, with the help of lanterns; while another story bears, that one of their emperors, displeased that his pleasures should be interrupted by the continual alternation of day and night, resolved, with the advice of one of his wives, to build a palace which should be impenetrable to the rays of the sun, which he lighted up with a multitude of lanterns, and in which he kept himself continually shut up amidst his dissipations; but that the people rose in a tumult, destroyed his palace, and drove him from his throne; and that the feast of lanterns is annually observed, at the date of this event, as a warning to voluptuous monarchs.

Feast of boats.

On the fifth day of the fifth moon is the feast of boats, which is said to have originated in a search made with boats for the dead body of a drowned mandarin. On this occasion, they make use of long narrow boats, painted with various figures, and containing often more than 60 rowers in each. These move along to the sound of drums and copper kettles, sometimes slowly, and at other times with great rapidity, striving to outstrip each other in their course; but, in this contest, boats are so frequently overset or dashed to pieces, and sometimes so many lives lost, that the mandarins often prohibit the celebration of the festival.

Solemn processions in time of drought;

In harvest

In honour of the dead

At Eclipses.

In the months of July and August, solemn processions are made, and in seasons of great drought, sometimes public fasts are observed, to supplicate the gods for rain, and to procure an abundant harvest. The country is at these seasons often covered with processions of this kind, accompanied with music, and carrying flags and small shrines, while the mandarins repair to the temples to intercede with the idols; and it is generally forbidden to kill a hog, or to eat flesh till the object of these petitions be granted. There are great processions in autumn, in which are carried lanterns, and large paper fishes; and four men support a table loaded with fruits, on which stands a young girl, with a younger one at her side, and another before dressed in the habit of an old man. The march begins with music and firing of crackers, while the inhabitants of the places through which the procession passes, cover tables at their doors with fruits, betel, and tobacco, which they present to the persons who compose the company. Similar processions also are made, chiefly during the spring months, in honour of the dead; and the order of march in these cases is generally as follows: A person first appears carrying gilded papers, followed by musicians, and children holding in their hands figures of men, horses, and birds, made of paper; next a company with lanterns, blue and white flags, parasols, and paper shrines; after these, a small wooden pagoda, attended by seven or eight bonzes uttering prayers; and last of all, a party well dressed, or clothed in mourning. Lanterns are lighted at the periods of new and full moon; and during eclipses of the sun or moon, when the Chinese imagine that these luminaries are in danger of being devoured by a dragon, then there is a general assemblage in every town or village, of mandarins, literati, citizens, and peasants, offering prayers for the safety of the labouring planet, beating upon drums and kettles to frighten the devouring dragon, and continuing the din without intermission till the termination of the eclipse. These and similar festivals may be regarded as the remains of the more ancient system; but the superstitions of the several later sects are incapable of arrangement or enumeration.

Temples.

There are numbers of temples and pagodas in every part of China, many of which are very extraordinary structures. These are in general named Miao, and may be distributed into two classes; first, those which are of considerable size, and which are well endowed with houses and lands; and secondly, those which have been built by private individuals, or a few priests; and one of this description may be seen in the vicinity of almost every palace belonging to the emperor. In every spot, also, where there is any kind of danger to be apprehended, small pagodas are erected, where travellers go to implore the protection of the spirit to whom they are dedicated; or, if they are prevented from entering the place, they burn their bits of paper, and beat upon their copper kettles as they pass. The temples have a great resemblance to the convents of Europe, are generally built in a simple style, and have their courts adorned with trees. They are constantly open; and at the entrance there is seen, in a hall or pavilion, a large drum and bell, upon which the worshipper strikes with a wooden mallet. In the apartment of the principal divinity, is placed a table covered with nosegays and vessels of perfumes; and a spiral candle composed of sandal wood and odoriferous gums is suspended before him, which is kept continually burning. In every city, almost, there is a temple dedicated to Confucius, as a tutelary spirit, in which either his statue or picture is preserved; and, in the seasons of spring and autumn, sacrifices are offered there in honour of this philosopher and his disciples, particularly by those who are about to undergo any literary examination. Besides these temples, numerous small chapels are to be seen in the country and villages, dedicated to the different spirits presiding over the land, the water, the mountains, &c.; but frequently, instead of a temple, there is merely a stone placed upright at the foot of a tree or bamboo bush, with the name of the tutelary divinity engraved upon it, and a few paper flowers by way of ornament.

Pagodas

One of the pagodas at Canton is thus described by M.

De Guignes; "After passing the two gates at the entrance, you find a court, which leads to two porches, one of which contains four figures cut in stone, in a sitting posture, and the other has four pavilions of two stories, full of idols. Around this court is a gallery supported by pillars, which serves as a place of communication to the cells of the ordinary priests, which are very small, and receive the light only by the door; and the principal priests have their habitations, consisting of two floors, at the angles of the square. In the middle of the galleries, are the dining-room and kitchens on one side, and the infirmary on the other. In the second inclosure is a herd of stags, and on one side several large fat hogs; and these animals having been devoted to the deity during the sickness of some bonze, are allowed to go at liberty till they die of old age." Another, dedicated to the goddess Poosa, was particularly noticed by Mr Barrow, in the province of Canton, which bore a great resemblance to the immense excavations and sculptures in the granite mountains of Hindostan. In the front of a rock, about 700 feet above the bed of a river, was a large cavern, with a terrace before it, accessible by a flight of steps; and from this cavity another flight of steps led to a spacious apartment, in the centre of which sat the figure of the idol upon a kind of altar, hewn into the shape of the Lien-hoa, or nelumbium plant. The sides of this place were covered with inscriptions carved or painted; and the whole rendered visible by a dim light through a small opening. The priests lodged in small caves, branching out from this large apartment. A third flight of steps conducted to a second story, with a small opening in the front, which was nearly filled with a large stalactite; and in this room was a gigantic image of a horrible aspect, with a crown on his head, a naked scymitar in one hand, and a fire-brand in the other, supposed to represent some deified hero.

The dragon is held in great veneration in China, and is called the spirit of the air and of the mountains. He is represented as covered with a buckler of tortoise-shells, sustaining the globe, and watching for its preservation. His figure is one of the imperial insignia; and the emperor alone has the privilege of wearing a dragon with five claws embroidered upon his robes.

Idols.

The temples in general contain an immense number of different figures, some of which are of a colossal stature; and these are generally placed at the entrance. They represent various genii, or guardian spirits, whose respective attributes are expressed by certain emblems connected with their statues. Thus, a sabre announces the god of war: a guitar, the god of music; a globe, the spirit of heaven. Some of these are frequently 30, 50, 60, and even 80 feet in height, with a multitude of hands and arms. One of the most stupendous in China is a goddess of the class of Poosa, which signifies all-helping, or plant-preserving, and is apparently a personification of nature. She is represented sometimes with four heads, and 40 or 50 arms, each of the heads being directed towards one of the cardinal points, and each of the arms holding some useful production of the earth; each arm also often supports a number of smaller arms, while the head is covered with a group of smaller heads. One of these idols, seen by M. Van Braam was 90 feet high, with four heads and 44 arms. The divinities in the interior of the temples are of smaller proportions, and in various postures; sometimes alone, and at other times surrounded by a number of inferior idols; some with the heads of animals, others with horns on the forehead; some reclining as at rest, others seated cross-legged upon flowers or cars; but all of them represented in a state of great corpulency, which the Chinese regard as an honourable quality. The idol Fo is seated upon a nelumbium flower, a species of water-lily. The goddess of lightning stands erect, with two circles of fire in her hand, and a poignard at her girdle. The spirit of fire walks upon burning wheels, and holds a lance and circle. The goddess of all things, named Teoo-moo, with eight arms, is seated in a chariot drawn by seven black hogs. The goddes Shing-moo, or Holy mother, the most ancient and common of all the female deities, whose character implies universal understanding, or more literally, "the faculty of knowing all that ear has heard, or mouth has uttered," was considered by the Catholic missionaries, as a shocking resemblance of their Holy Virgin. Her statue is generally represented with a glory round the head, and a child in her hand or on her knee, holding a flower of the Lien-hoa, (nelumbium,) or placed upon a leaf of that plant. Her legend is, that, when she was bathing in a river, she happened to eat a flower of the nelumbium, and immediately became pregnant; that when the period of her gestation was completed, she repaired to the same spot where she had first picked up the flower, where she brought forth a son, who afterwards became a celebrated personage, performed miracles, and gave laws to the whole empire. There are divinities, in short, of all possible shapes, and so numerous that one pagoda on the lake See-hoo contained 500 of them within its walls.

Deified men.

Among the multitude of figures of metal, stone, wood, or baked clay, painted, varnished, and gilt, with which the temples are crowded, are frequently to be seen the statues of emperors, mandarins, and other great personages, who have been friendly to the sect in general, or to that particular convent, or who have left a sum of money to procure a niche for their images among the divinities.

Household gods.

Besides these places of public resort, the Chinese have always an altar in their private dwellings, and a few small idols, before which they burn gilded papers, especially at the new and full moon; and there is generally placed upon their door the name or figure of the idol Men-shin, who is a kind of household god, and who is represented with a club in one hand, and a key in the other.

Bonzes.

The priests, officiating in these different temples, are either the followers of Tao-tse, or of Fo, the latter of whom are called Ho-tchang; but both are generally denominated by the name of Bonzes; and indeed they resemble each other so nearly in their appearance and functions, that they are scarcely distinguishable. The Bonzes of Tao-tse are generally devoted to celibacy, and associated in convents like the Romish monks. They wear a long robe, with large sleeves, and without a neck. They never shave their heads, but collect their hair upon the crown. In performing their worship, they move in procession round the altar, on which the sacred flame is kept burning, chaunting in recitative, and bowing their bodies as they come in front of the altar, while gongs and musical plates are sounded at certain intervals. In their dresses, altars, images, incense, bells, candles, chaunting, &c. they bear a striking resemblance to the Catholic exhibitions; and one of the missionaries, much hurt at the similarity, makes the following observations on the subject; "there is no country where the devil has so successfully counterfeited the true worship of the Holy Church. These priests of the infernal spirit wear long loose gowns, exactly resembling those of some of the fathers; they live in temples, like so many monasteries; and chaunt in the same manner with us." They sacrifice to their idols a hog, a fowl, and a fish; and then observe a multitude of ceremonies, incantations, mystical rites, and magical practices, which frequently vary according to the fancy or skill of the actor. They act also the part of fortune-tellers, in which they are sufficiently expert, representing the figure of their chief in the air, causing the pencil to write the oracular response of itself, shewing the figures of persons in a bason of water, &c. They attend at funerals, to drive away evil spirits; profess to cure the sick by their incantations or intercessions; and pronounce a benediction upon the ships, when first launched into the sea. They run about the streets lashing themselves, as an expiation for the sins of their votaries, and collecting money as the price of their services.

The priests of Fo live also in a state of celibacy, and in large convents, which the Chinese call Poo-ta-la, which is the mode in which they pronounce the word Buddhalaya, that is, the habitation of Buddha. They shave their heads, and wear long gowns, generally of a yellow or black colour, to which on days of ceremony they add a red bonnet and scarf. They have a kind of chaplet round their necks, consisting of a number of beads; and in some of their acts of worship they march, like the Tao-tse, round the altar, counting these beads as they move, at every bead bowing the head respectfully, and repeating the word O-mi to-fo; and when the whole string is finished, they make a mark with chalk, in order to register the number of their ejaculations to the god Fo. They eat no flesh, fish, or onions, drink no wine, and lead, in short, a very abstemious life; but are nevertheless, it has been observed, sufficiently fat and well grown.

The bonzes are generally regarded with contempt, as persons who deprive their country of that personal labour, which is counted in China as a sacred duty; and it is only persons advanced in life, or of the lowest class of people, who join their society. Hence it is their practice to purchase young children to learn and to perpetuate their system; and, to attract the greater respect and confidence, they employ every possible mode of acquiring riches, and securing reverence. When consulted with respect to the most fortunate spot for building a house or erecting a sepulchre, they have generally a secret understanding with the proprietor of the ground, which they pronounce to be the most desirable, and share with him the price of the purchase. To secure the protection of the emperor or chief mandarins, they place them among the number of their divinities; and to draw the populace to their temples, they announce prodigies of various kinds, and threaten dreadful transmigrations to those who neglect to bring offerings, and to secure the benefit of their prayers. In these offerings, animal victims are now rarely seen, on account of the great scarcity of sheep and the value of hogs; but fruits and roasted fowls are the principal gifts. Even these, however, are seldom left for the idol or the priests, but are carried away by the worshipper, after the invocation has been performed; and, in their stead, a sum of money is given to the bonzes of the temple. In these acts of devotion, it has been remarked that the Chinese appear to be actuated rather by a dread of some evil in this life, than the fear of punishment in another; that they perform their sacred rites more with a view to appease an angry deity, and to avert impending calamities, than from any hope of obtaining a positive good; that they rather consult or inquire of their gods what may happen, than petition them to accomplish or avert it; that a Chinese can scarcely be said to pray, but while he may be grateful when the event proves favourable, is petulant and peevish when it is adverse. They hold the different idols in more or less estimation, according to the favours, which they are supposed to have conferred upon their votaries; and when, after repeated applications, their suit is not granted, they abandon the spirit of that temple as a god without power, or perhaps pull down the edifice, and leave the statues exposed in the open air. Numbers of temples are thus seen in ruins, their bells lying on the ground, their monstrous idols standing unsheltered, and their bonzes wandering in quest of alms or a more fortunate asylum. Sometimes the fallen deity is treated with the utmost outrage and contempt. "Thou dog of a spirit," the enraged votaries will say, "we lodge thee in a commodious temple; thou art well gilt, well fed, and receivest abundance of incense; and yet, after all the care bestowed upon thee, thou art ungrateful enough to refuse us necessary things!" Then, tying the idol with cords, they drag it through the kennels, and bespatter it with filth. But should they happen, during this scene of vengeance, to obtain, or to fancy that they have obtained, their object, then they carry back the insulted divinity to its place with great ceremony, wash it with care, prostrate themselves before it, acknowledge their rashness, supplicate forgiveness, and promise to gild it again, upon condition that what is past be forgotten. Sometimes those, who have found all their gifts and worship unavailing, have brought the idol and its bonzes to a solemn trial before the mandarins, and procured the divinity to be dismissed as useless, and its priests to be punished as impostors.

Sacred offerings.

Pilgrimages.

Among the Chinese superstitions, pilgrimages are not wanting; and on certain mountains in every province are holy places, more or less revered, to which the more devout worshippers repair from immense distances, and which they are required to ascend by dragging themselves along on their bended knees. Such as are unable, by age, infirmities, or urgent avocations, to make their sacred journeys, commission their friends to bring them a consecrated leaf filled with various characters, and stamped by the bonzes, in the centre of which is a figure of the idol Fo, surrounded with a number of circles. Every time that they count over their beads at seasons of devotion, they make a red mark upon one of these circles; and this leaf, which is the register of their prayers, is occasionally laid before the bonzes, that they may attest the number of circles thus marked, and imprint their seal upon the record to render it authentic. This important memorial, which it requires considerable sums to render duly formal, is carried with great solemnity at the funeral procession of its possessor, deposited in a small sealed box, and considered as his passport to the other world.

Superstitions.

Every trouble in China is attributed to the influence of some evil spirit, which every one's imagination frames to himself, and which he places, as it pleases him, in an idol, an old oak, a lofty mountain, or at the bottom of the sea. These mischievous spirits are considered by some as the souls or purified aërial substances of animals, such as of foxes, apes, frogs, &c.; and these creatures are supposed to have the power, after living a certain number of years, to divest themselves of the grosser parts of their nature; and, after becoming pure essences, to take delight in tormenting human beings, especially by exposing them to diseases. Hence, in time of sickness, the principal remedy is to send for the bonzes, to banish, by their noises and incantations, those malignant spirits.

In every possible circumstance of life, the Chinese implore the protection and aid of some deity. Should a countryman be about to raise some large stone, or to at-

Lucky and unlucky days.

Calculation of their destiny.

tempt any work in which he might be in danger of receiving some injury; he places a small stone upright, surrounds it with a few candles, burns two or three gilded papers, and then applies to his labour with perfect confidence. When they have any dread of losing their children, they consecrate them to some divinity; and, in this view, they pierce the ear of the child, and suspend from it a small plate of copper, silver, or gold, with the name of the tutelary spirit inscribed upon it; or they simply tie the hair of the head on each side, into the form of a small tuft, which indicates that they are devoted to some god, who will preserve them from accidents and misfortunes. They pay great regard to lucky and unlucky days; and the government even publishes an annual calendar, in which, among other matters, the favourable moments in that season are properly marked. Midnight is always a lucky point of time, because in their opinion the world was created at that hour. But, of all their superstitions, the two following are the most prevalent, and form the chief object in their various acts of worship in the temples. 1. The calculation of their destiny, which they call Sooan-ming, and which is generally done by blind musicians, who go from house to house, playing on some musical instrument, and offering their services for a little money; whose art consists chiefly in astonishing their hearers by speaking learnedly of the position and influence of the stars, and in describing the proper idol to whom sacrifices must be offered, or the Bonze whose prayers must be secured. 2. The securing a good influence, and fortunate exposure, in building their habitations or sepulchres, which is called Fong shooy, "or wind and water." Upon this depends every one's success and happines in life; his natural abilities and genius, his advancement to honours, his commercial prosperity, good health, a numerous family, are all ascribed to his house or his burying-place having a happy situation, and his thus possessing a lucky Fong-shooy. They are constantly employed in devising means to render this circumstance or influence favourable. Much depends upon having the doors of their habitations placed under the protection of a proper spirit, arranged in a proper order, or constructed in a proper form. A round door is fortunate, and there is generally one at least in every Chinese dwelling. It is bad to have two doors directly opposite to each other, as the evil spirit, in that case, more easily enters. When this cannot be avoided, they put up screens of wood to stop the genius in his progress, or form their doors in the shape of a fan, a flower, a leaf, which all contribute to bewilder the malignant spirits, and to make them afraid to leap over. Should a neighbour build a house close to another, but not upon the same plan, or should there be any corner or slanting of the roof, so placed as to cross that of the other, this is enough to occasion desolation and distress to the proprietor, who lives in constant apprehension of some malignant influence. Should a law suit fail to relieve him from the adverse encroachment, his only resource is to raise on the middle of his roof an enormous figure of a dragon, in baked earth, darting a furious look upon the fatal angle, and opening its mouth so as to swallow the offending object: this removes all apprehension, and restores the tranquillity of the household.

Lots.

But, in both the last mentioned superstitions, great dependance is placed upon casting of lots, which is practised in two ways. One is to burn incense before an idol, which stands upon an altar, containing a number of small flat sticks, from eight to twelve inches in length, upon which are traced a variety of unintelligible figures, supposed to contain answers to the questions of every supplicant. After various prostrations and ceremonies, the person, consulting the oracle, draws out at random one of these small sticks, and receives an explanation from the Bonze, who accompanies him, or finds a tablet upon the wall of the temple containing solutions of the several enigmas. Another way is to take two pieces of wood, about six or seven inches long, cut in the form of a split bean; and to throw them up in the air, repeating the operation till they fall in a fortunate position. These consultations are accounted necessary before undertaking a journey, commencing a law suit, entering into the married state, building a house, or engaging in any important business. They are the chief occupation of the numerous Chinese who are seen in the temples; and, as they find these oracles in the pagodas both of Lao-tse and Fo, they repair to either of them indiscriminately.

The other religious sects, known in China, but who are chiefly foreigners, are Jews, Mahometans, and Christians.

Jews.

The Jews are supposed to have found their way into China, after Alexander, by his conquests in the East, had opened a communication with India; and their arrival in the country is said to be noticed in the historical records of China. The date of that event is fixed by some in the year 206, and by others in the year 258 before Christ. They abound chiefly in the silk provinces, especially in the neighbourhood of Hang-tchoo-foo, and are the best manufacturers of that article; whence it has been conjectured, that they first introduced the silk-worm into the empire. They are not very numerous, and are called by the Chinese, Hoey, or Lang-mao-hoey, that is, Hoey with the blue bonnets, because they wear a species of turban of that colour, when they assemble in their synagogues.

Mahometans.

Some Mahometans are supposed by the missionaries to have entered China about the year 599, which is however twelve years sooner than Mahomet appeared in the character of a prophet. Many learned Mahometans, from Balk and Samarcand, accompanied the Western Tartars when they invaded China, A. D. 1279; and were of great use to the vanquished Chinese, in improving their astronomy, correcting their calendar, and introducing the knowledge of various philosophical instruments. They became extremely numerous under the following dynasty of Ming, who expelled the Tartars, and began to reign A. D. 1368. The method, which they employed to increase their sect, was to purchase children, or to collect the foundlings, whom they educated in their tenets; and the various calamities of the times supplied them with many at that tender age, whom their parents were unable to support, or who had lost their relatives amidst the desolations of their country. There are not many of this sect in the body of the empire; but numerous tribes of them inhabit the extremities of the province Shen-see, distinguished by the Chinese into three different bodies, according to the mode in which they cover their heads. Of these, about 100,000 are supposed to have been cut off by the orders of Kien-long, during the insurrection which they excited in 1784.

Christians.

During the seventh century, about the year 635, a few Christians of the Nestorian sect passed from India to China; and were tolerated by the government nearly two centuries, under the designation of priests of Ta-tsin. But, in the year 845, they were proscribed by the emperor Voo-tsong at the instigation of some of his favourite Bonzes; and, after suffering a severe persecution, appear to have been completely extirpated. In the beginning of the 13th century, a number of Christians, of the Greek church, who had followed the army of Genghis-Khan, entered China along with the Tartars under Kublai khan; and received from that emperor a grant of a space of ground, within the walls of Pekin, for the purpose of erecting a church. Marco Polo, the celebrated Italian traveller, who visited China about this period, accompanied three missionaries of the Dominican order, who were sent from Venice to Pekin, at the express desire of Kublai-Khan; but, whether from a want of encouragement or of zeal, they returned in a short time to their native country with no small degree of wealth, acquired chiefly by trading in their progress through the East. About the middle of the 16th century, Francis Xavier, at the head of a company of Romish missionaries of the order of Jesuits, reached the island of San-shian on the coast of China, where he died in 1552; and, after a communication was opened with India by the Cape of Good Hope, a number of Romish priests passed into China to propagate the faith. In this view, they took care, in the first instance, to render themselves useful to the government as interpreters, astronomers, mathematicians, and mechanics; and, in general, found means to acquire wealth and respectability. The Portuguese particularly, who hold the highest stations in Pekin, are in possession of good estates and country seats; and the French Jesuits, before the dissolution of their society, were a very rich and powerful body in China. These missionaries, however, especially the Portuguese, are said to be extremely jealous and illiberal towards each other; and it was in a great measure owing to their frequent dissensions, that the Christians in China have been so severely persecuted. The most inveterate of these contests took place between the Jesuits and the Dominicans; the former of whom, by assimilating their opinions and practices in a great degree to those of the Chinese sects, and by professing, that they were come only to restore the ancient religion of the country to its original purity, when first delivered by their great philosopher Confucius, began to gain immense numbers of followers, who were half Christian and half Pagan in their sentiments and manners. The Dominicans, upon their arrival in the country, at once condemned these compromising arts, excluded these mixed proselytes from the number of Christian converts, and prohibited their followers among the natives from observing any of their ancient rites, especially from practising that fundamental national duty of sacrificing to their deceased relatives in the hall of Ancestors. The Franciscans adopted the sentiments of the Dominicans; and represented the conduct of the Jesuits to the Pope in such a point of view, that he sent out a bull to China, forbidding all the Catholic missionaries to permit the union of any idolatrous ceremonies with those of the church. But the Jesuits, whose superior talents and useful services had secured the protection and favour of the reigning sovereign Kang-hee, treated the injunctions of the Pontiff with contempt, and continued to make converts according to their own plan. They obtained a grant of land from the emperor for the purpose of building a church at Pekin; and received a dispensation from the succeeding Pope in favour of their proceedings in the conversion of the Chinese. Representations from the Dominicans and Franciscans were again transmitted to Rome, representing the Jesuits as the greatest enemies to the Christian faith; and these were followed by contra-remonstrances on the part of the Jesuits, with an attestation from the emperor himself, bearing, that the ceremony of paying homage to the dead, as practised by the Chinese Christians, was not of a religious but of a civil nature, and a duty which the political constitution of the empire rendered indispensable.

These disputes were at length carried so far, and the mandates of the Pope requiring the Chinese converts to desert those ceremonies which the government regarded as an essential law of the country, became so threatening and imperious, that the emperor at last conceived his authority to be attacked, and interdicted the Christian faith from being taught in his dominions. His son and successor, Yong-tching, began his reign with imprisoning, banishing, and putting to death the missionaries and their adherents in great numbers, and permitted only a few, whose assistance was needed in regulating the calendar, to remain in the metropolis. In spite of these persecutions, which have been renewed in every reign, and which particularly prevailed in the year 1785, numbers of new missionaries are occasionally making their way into the country; and two young men, under that character, requested and received permission to join Lord Macartney's embassy, and to proceed with him to Pekin. Missionaries. There are two kinds of missions in China; one which is approved by the government, and resides at Pekin, and which the Chinese now find essentially necessary in transacting many of their most important public affairs; and another in the empire at large, which the government does not avow, but which the mandarins are sometimes backward to detect, lest they should be punished for not having been sufficiently watchful to prevent the first entrance of the missionaries into the country, and are therefore not always very much disposed to question any one publicly respecting his faith. Both of these missions are often highly useful in a political view to the nation, with which they are connected; and we quote the following sentiments of M. De Guignes on the subject, as of no small importance in more respects than one. "The mission of the interior costs very little to support it. Men will not easily be found more virtuous and disinterested than those individuals, of whom it is composed. Deprived of all the comforts of life, subjected to every species of privation, and exposed every day to the risk of being put to death, nothing but the desire of acquiring information and propagating the Christian faith, could make them despise the evils which they endure. I speak here without prejudice; I relate what I have myself witnessed; and I feel myself constrained to speak the truth. The French government, by supporting missionaries, who pervade the vast empire of China, has always the power of procuring useful information, with respect to commerce, the situation of places, and a thousand other important objects. I am not the blind admirer of all missionaries; but I know many of them, whose attainments are very extensive, as their writings also sufficiently prove; and it cannot be denied, that we owe a great deal to those laborious and indefatigable men." "With regard to the mission at Pekin, its utility is sufficiently demonstrated by facts; and a person must be utterly blind not to acknowledge the importance of having one, duly authorised, at this capital. A similar establishment would be purchased with heaps of gold by a rival nation; and it would give any thing in the world to have the power of employing these means at its pleasure. As long as China shall remain shut against Europeans, the nation who shall preserve some individuals at Pekin, may account herself fortunate. By their means, she may be able to know, to prevent, to undertake every thing. I speak from known facts, but of which the details cannot be divulged. It is then, I repeat, of the last importance, Religion.

and a measure of the soundest policy, that the French government afford succour to the missionaries, and extend protection to those persons who are truly respectable." Missions, indeed, can never be considered as securely established in China, as the whole character and manners of the nation are against the progress of the Christian religion; and no dependence can be placed upon the natives, who will change opinions, every moment, according to circumstances. One great hindrance will always be found in the despotic nature of the government, which cannot endure that one of the people should have a single sentiment or observance, which it could not have power to alter or suppress. By letters received from Canton in 1802, it appeared, that the prohibitions against the Christians had greatly relaxed in their rigour; and that the emperor had actually issued an edict permitting the residence of the Roman Catholic missionaries in any part of his dominions, within twenty miles of the court; in consequence of which indulgence, it was added, that a number of converts had been baptized. It appears, however, from a subsequent edict, dated 1805, that the labours of some of those missionaries had excited the alarm of the government; and that a persecution was then carrying on against the Christians. The edict admits the right of Europeans, settled in the country, to practise their own religious usages; but declares it to be an established law of the empire, that they should not propagate their doctrines among the natives. A missionary residing at Pekin, and named Odeadato, who had made many converts, and also printed several religious tracts in the Chinese language, was banished for life to Gehol in Tartary; and a number of the Chinese, who had become Christians under his instructions, or been assisting to him in his plans, were condemned to suffer punishment, according to their respective degrees of guilt. It was further declared, that all, who shall hereafter frequent the houses of Europeans, in order to learn their doctrines, will be punished with the utmost rigour of the law.*

Laws.

The laws of China are directed by the government to be carefully taught to the people, by the mandarins of the respective districts; and it may be said, that jurisprudence is the only religion, which is inculcated by authority in this vast empire. The laws are also published for the use of the subjects, in the plainest characters of the language, and in a popular and easy style. A republication takes place, at the accession of every new dynasty, of the subsisting statutes, which forms the Leu, or fundamental code, during the continuance of that family; and to this, as supplementary clauses, are appended all the additional statutes, under the title of Lee. The earliest compilation of which any intelligence has been procured, is ascribed to a person of the name of Lee Quee, who is supposed to have lived about 250 years before Christ; and the greater part of the existing laws of China are conceived to be as ancient as that period. The present system of Chinese laws is called Ta-tsing-leu-lee, and takes its date from the year 1664, when the present Tartar dynasty of Ta tsin ascended the throne. The substance of this work has been translated into English by Sir George Staunton; and we may thus have a more thorough knowledge of the legislation of China, than of any other subject respecting that country, to which our enquiries can be directed. The laws also enter so minutely into every circumstance of private life, that a perusal of the work in question would afford a very complete view of the manners and customs of the Chinese people. For the sake of those, however, who may not have the opportunity or the wish to examine that large compilation, we may here insert a few of its principal enactments, as a specimen of its contents, and as the most authentic information on this branch of our subject.

These may be arranged under the following heads, viz. the different kinds and degrees of punishment authorised by the laws of China; the principal regulations, which they ordain in some of the most important and interesting cases; and the mode of administering those laws, in the apprehension and trial of delinquents.

Punishments.

In the time of Confucius, there were five sorts of punishments; viz. a black mark upon the forehead, amputation of the tip of the nose, amputation of the foot, or cutting of the ham-string, castration, and death. None of those punishments are mentioned in the code of the present dynasty; but those which are in common use, are,

1. The bastonade, which is inflicted by the pan-tse, or bamboo. This instrument is a lath of bamboo, about five or six feet in length, and four inches in breadth at the end which is applied to the offender, rounded at the sides, and polished at the extremity which is held in the hand of the executioner. It is generally applied in a severe and cruel manner, and it is seldom that a delinquent survives after receiving fifty blows. This instrument is in constant application, and is inflicted for the smallest offence. The more ordinary chastisements are not attended with disgrace, and are considered merely as a slight paternal correction. It is said to be frequently inflicted in this view, by the emperor himself, upon his courtiers and prime ministers, without their forfeiting his favour, or losing their respectability with the nation; and one officer may apply it to another of an inferior order, in a very summary manner, upon his failing in any duty, or even neglecting to salute his superior with pro-

---

* Some of the Christian associations in Great Britain have recently turned their attention to the practicability of sending the sacred scriptures to the Chinese. In 1802, a note was sent by the Archbishop of Canterbury to "the Society for promoting Christian Knowledge," accompanied with a copy of a memoir by the Rev. W. Mosely, "on the importance and practicability of printing the sacred Scriptures in the Chinese language, and circulating them in that vast empire;" and, upon a motion by the Bishop of Durham, the matter was referred to the East India Mission Committee. The same idea had occurred to the British and Foreign Bible Society; and a young Chinese then residing in London, named Yong-saam-tak, had been employed by them in transcribing a Chinese translation of a harmony of the gospels, and most of the epistles, which had been found in the British museum; but it was discovered, upon examination, to have been made from the Vulgate, probably by some Jesuit, and the work was abandoned. This great object has since been undertaken, and in a great measure accomplished, by the Baptist missionaries in Bengal, with the assistance of a learned Chinese; whose important labours was noticed with just commendation by the present Governor-General in India, in the following impressive language: "I must not omit to commend the zealous and persevering labours of Mr Lassar, and of those learned and pious persons associated with him, who have accomplished for the future benefit, we may hope, of that immense and populous region, Chinese versions, in the Chinese character, of the gospels of Matthew, Mark, and Luke; throwing open that precious mine, with all its religious and moral treasure, to the largest associated population in the world." A similar attempt is making also by a Mr Morrison at Canton, who was sent to that station by the London Missionary Society; but, in the year 1809, he had still no prospect of being able to make his way to Pekin. In 1810, he had printed 1000 copies of the Acts of the Apostles, in the Chinese language and character; and, as he understood that the Gospels and Epistles were preparing at Calcutta, he had begun to translate the book of Genesis and the Psalms. He has lately published a work entitled *Horæ Sinicæ*, consisting chiefly of translations from the Chinese.

per respect. When it is inflicted in a court of justice, the presiding mandarin takes a small stick, about six inches in length, and one in breadth, out of a bag placed before him, and throws it upon the ground. The culprit is instantly seized by the attendants, and stretched upon his face on the earth, his clothes pulled down to his heels, and five smart blows applied to his posteriors; and, for every stick that the mandarin throws from his bag, five additional blows are inflicted. The offender must then throw himself upon his knees before the judge, incline his body to the ground, and give him thanks for the care which he takes of his morals: This is affirmed to be done even by the higher officers to their superiors. When women are subjected to this punishment, they are permitted to wear an upper and under garment, except in cases of adultery, when they are allowed only the under garment. It is said, that a Chinese, when undergoing the bamboo, cries out in a most piteous manner, and makes his acknowledgments afterwards with the utmost humiliation; but that a Tartar generally suffers in silence, grumbles against the executioner, and at length sullenly retires. In the case of mandarins, corporal chastisement may, in ordinary cases, be commuted for fine or degradation, or entire dismissal from the service of government.* The near relation, also, of a convicted offender, may put himself in the place of his friend, and undergo the legal punishment, provided that it be slight. It is affirmed, even that there are persons who make a trade of offering themselves as substitutes on these cases, and who are freely admitted by the judges. These persons contrive to escape without much injury, by sharing their pay with the executioner; as the actual offender also may do, when he submits in person, in the following manner: When the delinquent or substitute is stretched upon the earth, and the executioner ready to strike, he raises his fingers, in what number he thinks proper, each of them expressing a certain number of the smaller coins. The soldier understands the signal, appears to strike with all his force, but takes care to make the end of the bamboo touch the ground; and thus the sufferer, though he does not fail to utter loud cries to keep up the deception, retires without having sustained much injury.

2. The tcha, a kind of moveable pillory, is a wooden collar, composed of two flat pieces of timber, hollowed out in such a manner, that, when united together, there is room for a man's neck to be inclosed between them. This instrument is generally about three feet square, and six inches thick; and the ordinary weight is between 60 and 70 pounds; but this is increased according to the degree of guilt, and sometimes amounts to 200 pounds. When this machine is placed round the neck, and resting on the shoulders, the criminal is unable to see his feet, or to put his hands to his mouth, and would die of hunger if he had no person to administer his food. There is always a paper attached to this collar, expressing the crime and penalty of the wearer; and he is not permitted to conceal himself at home, or in retired situations, but is condemned to appear a given time every day in some public square, street, gate, temple, or tribunal. It is worn night and day, and the offenders can be relieved from the weight only by leaning the corner or side of it upon the ground; but sometimes they are seen provided with a bamboo chair, the sides or posts of which are raised so high as to support the tcha, without allowing it to touch the shoulder. There is still, however, no rest found for the head; and this situation is prolonged for weeks, or months, according to the nature of the crime. At the expiration of the assigned period, the culprit must present himself before the judge, who relieves him from his load, exhorts him to amendment, and dismisses him with a slight chastisement from the bamboo.

3. Banishment to different distances for different periods, or to the regions of Tartary for life; and persons suffering this sentence are obliged to wear a red cap. The children, grandchildren, and wives of an exile, are permitted to follow him to his place of residence.

4. Dragging the imperial barks for a certain number of years, and within a certain range, 200, 250, or 300 leagues, according to the degree of delinquency. This punishment is not very frequent, perhaps, because a certain number of persons only is required for the purpose, and a multitude of culprits would too much diminish the labour.

5. Death by strangling or beheading. The former punishment is not inflicted by suspension, as in Europe, but a running noose is put round the neck of the criminal, and two attendants pull the cords in different directions, with all their might, suddenly quit their hold for a moment, then give a second pull, which generally completes the business; or, the criminal is tied upright to a cross, a rope passed about his neck, and twisted strongly behind by means of a stick, or bow, in the hand of the executioner. The latter punishment, that of beheading, is accounted the most infamous; and as the Chinese consider the loss of any member, with which they have been born, as one of the greatest misfortunes, they have a peculiar horror of suffering decapitation, and of thus dying in a mutilated state, deprived of the noblest part of the body. Sometimes the head of the criminal, especially of an assassin, is exposed in a cage suspended from a post erected at the side of the high way. Persons guilty of high treason, are put to death by a slow and painful execution; and, though it is sometimes specified, that this shall be done by opening the belly of the criminal, and then cutting his body into several pieces, yet it is permitted to the executioner, in general, to aggravate and prolong the sufferings of the condemned, by any species of cruelty which he may choose to inflict. In cases of capital punishment, the sentence cannot be executed till the emperor has examined and confirmed the process. When the crime is of an atrocious nature, the execution is ordered to take place without delay; but, in general, it is postponed till the season of autumn, when all the sentences of death are inflicted throughout the empire. Before any offender is put to death, a meal is set before him; and he may be conveyed to the fatal spot by a chair, or carriage, if he has the means to procure it. His mouth is gagged, and the judges are present at the execution. In some rare cases, the sentence of death may be redeemed by a sum of money, from L. 400 to L. 4000, according to the rank and ability of the offender. Persons below ten, and above eighty years of age, when guilty of a capital offence, are recommended to the emperor's clemency; and no one below seven, or above ninety, is made to suffer death for any crime except high treason.

Torture.

In cases of great moment, the accused are authorised to be put to the torture, in order to extort confession;

---

* In the case of persons under fifteen, or above seventy years of age at the time of their trial, whatever may have been their age at the time of committing the offence, corporal punishment may be redeemed, at the rate of about thirty shillings a blow.

and this is applied to the hands or to the feet. The former is inflicted by means of round pieces of wood, about an inch thick and a foot long, which are placed between the fingers, and drawn together at the extremities, in such a manner as to dislocate the joints. The latter is done with three pieces of wood, one of which remains fixed, and is put between the two ankles; the other two are moveable, about three feet in length, and six inches wide, fastened together at one extremity by a hook, and pulled close at the other end, by means of cords passing through holes, with such force as to render the ankle joints flat. These racks are understood to be extremely painful; and yet it is affirmed, that, by means of proper applications, persons who have undergone the latter operation, were often enabled to walk again without difficulty. A still more dreadful kind of torture is mentioned, which consists in making small gashes in the body, and then tearing off the skin in the form of thongs: It is sometimes used in cases of treason, or other atrocious crimes, when the guilt of the sufferer is clear, and when it is wished to make him discover his accomplices; but in these cases, it seems to come rather under the denomination of capital punishment, as already described. Torture cannot be inflicted upon the eight higher orders of princes and officers, upon persons under fifteen or above seventy years of age, or upon those who labour under any permanent infirmity or disease.

The scale of punishment consists of five divisions, in each of which there are various gradations.

1st, From 10 to 50 blows of the bamboo.

2d, From 60 to 100 blows.

3d, Temporary banishment to a distance not exceeding 500 lee, or 150 miles, extending from one to three years, and accompanied with a corporal punishment from 60 to 100 blows.

4th, Perpetual banishment to the distance of 2000 or 3000 lee, with the additional punishment of 100 blows; and,

5th, Death by strangulation, decollation, or torture.

Specimens of laws.

Treason.

1. These laws are particularly severe with respect to all offences committed against the sovereign; and his life and authority are guarded by the most minute and cautious regulations. Persons, convicted of treasonable practices, are to be put to death by slow and painful tortures; all their male relations, in the first degree, indiscriminately beheaded, their female relations sold into slavery, and all their connections, residing within their household, relentlessly put to death. To intrude even into the line of the imperial retinue, while the emperor is travelling, or to enter any of the apartments in the palace, actually occupied by himself or his family, is punishable with death. Nay, to walk or ride upon the road and bridges, along which the emperor is to pass, exposes the offender to severe punishment. All the workmen employed about the grounds and buildings in the palace, have their names inserted in a list as they go in and come out; are provided with passports as they enter the gates, which they must deliver back at their return; are regularly counted, as they pass and repass; and, if any one remains behind, he is subject to a capital punishment. If the emperor's physician compound any medicine for the use of the sovereign, in a manner which is not sanctioned by established usage, he is subject to the punishment of 100 blows. If any dirt is found in his majesty's food, the cook is condemned to receive 80 blows; if he sends up any dish, which he has not previously tasted, he receives 50 blows; if he has mixed any unusual ingredient in the food, he is liable to 100 blows, and is compelled to swallow the article himself.

Homicide and murder.

2. The life of man is held peculiarly sacred; and, except in the case of exposing infants, murder is never overlooked. Murder by design is punished by beheading. Administering poison is a capital crime, though the dose should not occasion death. Killing in an affray is also punished with death. Homicide, or even wounding by accident, is still punishable with death; but the offender may in this case redeem himself from the capital part of the sentence, by paying a fine to the relations of the sufferer, to defray the expence of his funeral. The mere attempt or design to commit parricide is punished by beheading; and the actual perpetration of this crime, by death with torture. A practitioner in medicine, performing any operation, or administering any medicines, in a manner contrary to the established rules and practice, and thereby occasioning the death of his patient, is considered as guilty of homicide; but if, upon examination, it appears to have been simply an error, he may redeem his life by a fine, upon the condition that he quit his profession for ever. To kill another in revenge for the slaughter of a parent is punishable only by 100 blows; and husbands are permitted to kill persons taken in adultery. In cases of assault, a multitude of nice distinctions are made, according to the degree of pain or injury inflicted; the rank and connection of the parties; and the degree of provocation given and received. Persons inflicting wounds are liable for their consequences, 20, 30, or 50 days, according to the nature of the injury; but, after the legal period is expired, the assailant is no longer responsible, even though the death of the other party should ensue. To strike a father, mother, grandfather, or grandmother, is punishable by beheading; and should a wife strike her husband's relations in any of these degrees, she is punished as if they were her own. Should she strike her husband, she is punished by three degrees more severely than for a common assault; if she maim him, she is put to death; and if he die in consequence, she is executed by torture. A slave, striking a free man, suffers only one degree more severely, than in the case of assault between equals, and *vice versa*. A master may strike his slave with impunity, provided it be for correction, and that the blow does not cut. A parent, chastising his child so as to occasion death, is punishable only by 100 blows; and no statute whatever exists against infanticide. Anonymous accusations are punished with death, even although they should prove true; and false and malicious accusations subject the offender to a penalty, two degrees more severe than the accused would have undergone, had the charge been proved.

Theft.

3. Theft, merely attempted, is punished with 50 blows; if actually committed, by a punishment from 60 blows, to 100 blows, or to death, in proportion to the value stolen; and, if against relations, or connections by marriage, the penalty is five degrees less than in ordinary cases; because all the members of a family are considered as having a joint interest in their property, so that the domestic thief takes what is partly his own. Swindling is punished by the same degrees as theft to the same amount; but, if the money was extorted by threats, the penalty is one degree more severe, than in ordinary cases of theft. Kidnapping and selling free persons as slaves, is punished with 100 blows and perpetual banishment; but, if force was used and wounds inflicted, by death. An attempt to rob in a body is punished with perpetual banishment. A single person, taking openly and by force the property of another, suffers 100 blows, and three years banishment; but, if the plundered individual be wounded, the penalty is death. Robbery during the night is punished with death; entering a dwelling-house

under night, by force or stealth, incurs a penalty of 80 blows; and the master of the house is justified in killing the person while he is entering, but not after he has succeeded in seizing him. Combinations to raise the price of commodities, are punished with 40 blows; and the use of false weights and measures, with 70.

Adultery.

4. Fornication and certain detestable crimes are punished with 70 blows; adultery with 100 blows, but more severely if committed by persons high in office; and rape subjects the offender to death by strangulation, while the attempt itself is punished with 100 blows, and perpetual banishment.

Fire-raising.

5. Wilful fire-raising in a person's own house, is punished with 100 blows; in the house of another, by death. Accidentally firing one's own house incurs a penalty of 40 blows; but, should the fire spread to the gate of an imperial palace, death is the consequence.

Forgery.

6. Forging an imperial edict, or counterfeiting the current coin of the empire, is punished with death; but there appears no precise regulation about the forgery of private writings.

Bribery.

7. Bribery is punished in different degrees, according as the sum is large or small, and the object innocent or criminal; and the penalties vary from 60 blows to death, which last is incurred by taking 80 ounces of silver (about £26.) for an unlawful purpose, or 120 ounces (£40.) for a lawful object. Offering or giving a bribe is punished less severely than accepting; and agreeing to accept is punished as if actually taken; but, when it is asked or extorted by an officer of government, the giver is not punishable at all.

Peculation of public money.

8. Very strict regulations are enacted for accurately keeping and auditing the public accounts, and for preventing the embezzlement of the public money. In all cases of defrauding the public, restitution is an indispensable obligation, independent of the prescribed punishment. Privately lending or employing the government money, is punished as theft according to the amount; and actual peculation, to the amount of 1000 ounces of silver, is punishable with death. The revenue officers are reciprocally answerable for each other; but it is rather strangely enacted, in all cases of officers under government, associated in one department, and committing offences against the laws as a public body, by false or erroneous decisions, that the clerk of the department shall be punished as the principal offender, the deputies, or executive officers, one degree less, the assessors another degree less, and the presiding magistrate less by a third degree.

Smuggling.

9. Smuggling is punished nearly as in Great Britain, but the penalties are rather milder. The carriage, boat, or horses, by which the unlicensed goods are transported, are forfeited as with us; but the offender forfeits only one half of the goods, three-tenths going to the informer; and the personal pains are moderate.

Marriage.

Divorce.

10. The regulations on the subject of marriage are remarkably full and precise. Almost every man is married as soon as he is of age; and the contract, in the case of a first and legal wife, is always concluded between the parents or relations of the parties, totally independent of their consent. After this, the husband may espouse other wives, or concubines, or handmaids, or by whatever other name he may choose to call them, without consulting his friends or observing any ceremony; but these inferior wives, though equal in rank among themselves, are all subordinate to the first wife. Persons bearing the same family name, though no way related to each other, are strictly prohibited from intermarrying; but even relations, beyond the fourth degree, may marry without any censure. Whoever marries, while his or her parents are in prison charged with a capital offence, incurs a penalty of eighty blows, unless the marriage has been consummated by the desire of the parents themselves, and the usual entertainments omitted. If a husband degrades his first wife to the condition of an inferior wife, he is liable to a punishment of 100 blows; if, in the lifetime of his first wife, he raises an inferior wife to the condition of a first wife, he is punished with ninety blows; and, in both cases, the wives are replaced in their former situations. If the wife commits adultery, the husband not only may, but must put her away, otherwise he would suffer a punishment of eighty blows; and, if he should repudiate a first wife, without a sufficient legal cause, he is punished in every case, with eighty blows. The justifying causes of divorce, besides adultery, are; barrenness, lasciviousness, disregard of the husband's parents, talkativeness, thievish propensities, envious and suspicious temper, inveterate infirmity; yet, if any of the three reasons against a divorce should exist, if the wife has mourned three years for her husband's parents, if the family have become rich, after having been poor previous to and at the time of marriage, or if the wife have no parents living to receive her back again; then none of the seven aforementioned causes will justify a divorce; and the husband, who puts away his wife upon such grounds, shall suffer punishment, two degrees less, than that last stated, and be compelled to receive her again. If a wife withdraws herself privately from her family, the husband may treat her as no longer his wife, but his slave, whom he may keep or sell to another in that capacity. If a husband absents himself three years from his wife, she may lay her case before the mandarins, and will then be permitted to take another husband.

Inheritance of property.

11. With respect to inheritance, it appears, that land cannot be disposed of by will contrary to the regulations of the law, which require the heirs to share it amongst them in certain established proportions. A son is always a minor during the life of his father, and whatever he inherits or acquires is entirely at his father's disposal; while he, on the other hand, is liable for his father's debts, except those incurred by gaming. Women are excluded from inheriting or disposing of property when there are children; but when there are no sons, a man may leave his whole property by will to his widow. The reasons given for not permitting females to inherit is, that a woman can make no offering to deceased relations in the hall of ancestors; and it is deemed one of the first blessings of a man's life to leave some descendant who can transmit his name to posterity at this public solemnity.

Debtors.

12. It does not appear that a creditor can attach the person of a debtor; but, upon a complaint being presented to a mandarin, he commands the goods of the debtor to be seized and payment to be made; or, if he has no substance to procure his discharge, he receives thirty blows, and a month's delay to make payment; and so on, at the rate generally of thirty blows per month, till he satisfy his creditor. Hence every possible exertion is made to discharge the claim; and sometimes the debtor gives himself up as a slave, when he has no other means of extricating himself from his difficulties. Though the law punishes with eighty blows every creditor, who should attempt to pay himself, by a violent seizure of what belonged to the person, who was indebted to him, yet certain modes of teazing the creditor at the commencement of the year are tolerated by the mandarins, and are generally accompanied with success. On the first day of the year, creditors enter the houses of their debtors,

announcing their claims with a loud voice, and continuing to keep their station, till they be reimbursed; and, as the debtor knows, that, should any accident happen to his creditor in such circumstances, he would be punished upon suspicion of having attempted his life, hence these visits are greatly dreaded, and are terminated if possible by actual payment, or by some compromise for the satisfaction of the claimant. Another, and generally a last resource, is to threaten to carry off the door of the debtor's house or shop, on the first day of the year, which is accounted the greatest misfortune, that could happen at such a time, as there would then be no obstruction to the entrance of the evil genii. As such charges for debt are accounted highly infamous among the Chinese, the friends and relatives of the party involved are ready to come forward with their mediation, to prevent matters from coming to such extremities; but, when a debtor is conscious of having no resource, it is no uncommon expedient, in order to avoid these inauspicious visits of his creditor, to set fire to his own house at the end of the year.

Private offences.

13. The laws interfere in every circumstance of human conduct, and penalties are incurred by the most private domestic improprieties, such as neglecting to honour the tombs of deceased parents, dressing unsuitably, allowing lands in possession to lie waste, neglecting to pay interest regularly for debts or borrowed money.

Forms of process, &c.

In matters of police, the process is very summary, especially if the mandarin has been a witness of the offence. He does not wait till a complaint be made, nor does he send the person apprehended to prison, to be brought afterwards to trial; but instantly interrogates, judges, and punishes him, upon the spot. When an individual has sustained any injury, he states his grievance to the mandarin of his district or village, who is ordained to administer justice without any fee or present, and who is forbidden to drink wine before going to the tribunal; and it is permitted to the subject, in every instance, to apply to the highest magistrate within his reach, to the governor of the city, or the viceroy of the province in which he resides. If the mandarin admits the charge, he puts upon it a red mark, which then converts it into a warrant for execution. In complicated cases, the trial is carried on in public and by writing, witnesses are examined, the parties heard, and the judge explains the ground of his sentence. No advocate or counsel is permitted, but every one pleads his own cause, either *viva voce*, or by memorial; and should any third person interfere in a cause, so as to give it an unjust issue, he would be subjected to severe punishment, according to the nature of the case. In criminal cases, the witnesses are confronted, and also separately examined; all possible means are used to reach the truth, and the whole process is committed to writing. If it is a matter of life and death, it is remitted to the tribunals at Pekin, where the whole is revised, and confirmed or altered, as they may see cause. But, in civil causes, the power of the superior magistrate in the place is absolute; and his decision without appeal, unless the matter be considered of sufficient importance to be transmitted to the capital. All persons, who come to the knowledge of a crime, and fail to inform, are liable to punishment; but whoever should inform against his father, mother, grandfather, grandmother, uncle, or elder brother, is condemned to suffer 100 blows, and to be banished for three years, even though the accusation should be just. In cases of theft and robbery, the mandarins and soldiers of the district are exposed to repeated floggings, or to dismissal from their office, if they fail to discover and convict the offender. If any one comes before a magistrate, and freely confesses his crime before he has been charged with it, he is entitled to a free pardon, provided it be the first offence. When once a person is apprehended upon any charge or suspicion, he is carried to prison without any relief, analogous to bail; except in the case of female offenders, who are not committed to prison, unless for capital crimes or adultery, but are permitted to remain with their husbands or relatives, till the day of trial.

Prisons.

There are prisons in every city of consequence, which are said to be large, commodious, and in excellent order. They are surrounded with high walls, in which are lodgings for the soldiers; and have large courts, where the prisoners are allowed to walk during the day. As their allowance of rice from the government is small, they are permitted to work for their support, and hence the prisons are provided with workshops, and the necessary articles of the different professions. In the larger prisons, merchants, tailors, butchers, and cook-shops, are to be found for the use of the persons confined; and, if the prisoners possess money, and have been guilty of slight faults, they can procure separate cells and good treatment. Their relations are allowed to visit them in prison, and are even encouraged to afford them every assistance and comfort in their power. The debtors and felons are always kept in separate apartments; and the latter are neither allowed to go out, nor to speak to any person. They bear a piece of wood upon their neck, upon which is written their name, crime, and sentence. They may be allowed to work, and to enjoy some little ease during the day; but are strictly treated during night, lest they should effect their escape, for which the soldiers would be held strictly responsible. They are then stretched upon planks of wood; tied down by large chains on their feet, hands, and body, stowed close to each other, so that they can scarcely stir; and are even covered above with large tables of timber. The women, also, are separated from the men, and can be seen and spoken to only through a grate or the turning-box, by which their food is conveyed. A mandarin is appointed to inspect frequently these places of confinement; and is bound to see, that the sick be properly treated, provided with medicines, and attended by a physician, at the expence of the emperor. Upon the death of a prisoner, the emperor must be immediately informed, and he sometimes commissions a higher mandarin to enquire how far the inspecting officer has done his duty. The body of a deceased prisoner is not carried out by the ordinary gate, but by a hole in the wall, made for the purpose, which is accounted one of the most infamous occurrences in the life of a Chinese; and one of their heaviest imprecations upon another, is to wish, that he may be carried through the hole. Hence, when a person, possessed of any property or station, falls sick in prison, his relations use all means to procure his dismissal till cured, that, in case of his dying, he may thus avoid the fate of being carried through the wall.

Character of their laws.

These laws are expressed in a style distinguished for its brevity, distinctness, and simplicity, yet sufficiently copious and full, so as to put it in the power of every subject, who peruses them, to understand the will of the legislature. The characteristic defect of the whole system is an unprofitable minuteness of regulation, an intolerable interference with every ordinary duty of life, and an unnecessary endeavour to fix every shade of distinction, which a case may receive from its circumstances. Thus, indeed, nothing whatever is left to the discretion of the judge, and every offender may almost anticipate his sentence; but the system is completely destructive of personal freedom, and resembles more the irksome discipline of a school, than the judicious restraints of an enlightened government. It is sufficiently adapted to keep subjects in order, and to repress private injuries among individuals; but it is a dead weight upon every thing like dignity of mind or delicacy of feeling, and would be felt as the most cruel oppression by a high-spirited and generous-minded people. The formation of such a code seems to belong to a state of society, not much advanced beyond the first stages of civilization, and its direct tendency evidently is to prevent the people, under its influence, from making any farther progress in the political improvement of their condition, or in personal refinement of character. The indiscriminate frequency of corporal punishment must infallibly prevent such attainments, and fixes the subjects always in the condition of grown children, who are kept in order by mere flogging. Offences of all descriptions, and in every rank of society, are punished by a certain quantity of flagellation; and there are at least 50 clauses in this code of laws, by which a general officer is ordered to receive, for particular offences, 50 lashes upon his posteriors; while he is allowed to continue in the command of the army. Such a system of whipping men into good morals and civil manners may be adapted to the peculiar genius of the people among whom it prevails; but it could never have originated, nor have continued to be endured, except in a country where there existed, in an extreme degree, a general debasement of all character. The severity of these corporal punishments is not so great as the law prescribes; and in the published code, we see rather the measure and scale of punishment, than the actual execution and practice. Thus, 10 blows of nominal punishment are reduced to four in reality, and 100 to 40. It is found, however, to depend much upon the administrators of these laws, whether they can be called lenient or severe; and it seems to be the concurrent testimony of eye-witnesses, that the latter character is the more general. "The manner," says M. De Guignes, "in which I have seen the bamboo applied during my journey is cruel." "In our return down the Pei-ho," says Mr Barrow, "the water being considerably shallower, than when we first sailed up this river, one of our accommodation barges got aground in the middle of the night. The air was piercing cold, and the poor creatures, belonging to the vessel, were busy until sun-rise in the midst of the river, using their endeavours to get her off. The rest of the fleet had proceeded, and the patience of the superintending officer at length being exhausted, he ordered his soldiers to flog the captain and the whole crew, which was accordingly done in a most unmerciful manner; and this was their only reward for the use of the yacht, their time, and labour for two days. Whenever the wind was contrary, or it was found necessary to track the vessels against the stream, a number of men were employed for this purpose. The poor creatures were always pressed into this disagreeable and laborious service, for which they were to receive about 6d. a day so long as they tracked, without any allowance being made to them for returning to the place from whence they were forced. These people, knowing the difficulty there was of getting others to supply their places, and that their services would be required until such should be procured, generally deserted by night, disregarding their pay. In order to procure others, the officers dispatched their soldiers to the nearest village, taking the inhabitants by surprise, and forcing them out of their beds to join the yachts. Scarcely a night occurred, in which some poor wretches did not suffer the lashes of the soldiers for attempting to escape, and for pleading the excuse of old age and infirmity. It was painful to behold the deplorable condition of some of these creatures. Several were half naked, and appeared to be wasting and languishing for want of food. Yet the task of dragging along the vessels was not light. Sometimes they were under the necessity of wading to the middle in mud; sometimes to swim across creeks, and immediately afterwards to expose their naked bodies to a scorching sun; and they were always driven by a soldier, or the lictor of some petty police officer, carrying in his hand an enormous whip, with which he lashed them with as little reluctance, as if they had been a team of horses." Nor is it merely the lower and poorer classes, who are thus subjected to the caprice, cruelty, and extortions of the mandarins; but even persons of property have no sufficient security or proper influence in this country, and are even still more frequently made objects of plunder to those in power. Hence a rich man in China, instead of deriving benefit or comfort from his wealth, is often afraid to use it, or at least to show that he is using it; and is very cautious not to indicate his circumstances by having a fine house, or wearing finer clothes than his neighbours, lest he should attract the notice of the governor of his district, who would soon find means to bring him under some sumptuary law, and thus to fleece him of his wealth. Thus it is always found in China, that the man in office has it in his power to govern the laws; and though the utmost solicitude is expressed by the imperial edicts, and the most severe restrictions enacted, with a view to prevent the negligence, corruption, and oppressions of the judges and officers, yet these are very generally disregarded by those who should most observe them; and there is scarcely a more profligate and oppressive government in the world, than that of the Chinese. Of one crime at least, and that one of the most heavily reprobated by their laws, they are known to be almost universally guilty, namely, that of corruption; and wherever this evil is so extensive, it is evident that the foundation of all justice and good government must be completely subverted. At Canton, it is believed that the British traders have never yet met with any officer of government, who was inaccessible to a bribe; and a very remarkable instance is recorded by Sir G. Staunton, in the appendix to his translation of their penal code, which will convey the best idea of the corrupt chicanery and barefaced falsifications which are common in Chinese tribunals of justice.

Instance of Chinese justice.

In February 1807, 52 seamen belonging to the East India Company's ship Neptune, having been on shore at Canton, had been involved in a general scuffle with some hundreds of Chinese, when one of the latter received an unfortunate blow with a stick, in consequence of which he soon after died. The Chinese merchant, who had become surety for the good behaviour of the crew, being called upon by the mandarins, applied to the British factory to deliver up the offender, or at least one of the seamen engaged in the affray. As it was impossible, however, to ascertain which of the ship's company, or whether any of them had given the blow, the supercargoes resisted the demand. The chief of the factory was threatened with imprisonment, until a man should be given up; the cargoes for the Company's ships were withheld; and the security-merchant was actually put in chains, and menaced with corporal punishment. As these measures did not succeed, the magistrates next demanded, that those seamen who were most active, who carried sticks, or who were known to be drunk at the

Laws.

time of the encounter, should be examined by torture. This demand was of course also rejected; and, after a month spent in threats, proclamations, and daily conferences on the subject, the security-merchant was allowed to send his agent to all the ships in the river, offering a reward of 20,000 dollars to any person who should give information of the individual who had struck the deceased. This temptation, great as it was, had no influence upon any of the British seamen, and at length the Chinese judges agreed to attend at the British factory, and to examine the 52 men in the ordinary way. Of these they selected eleven as having been the most active in the scuffle, and endeavoured to prevail upon some one of them to plead guilty, under an implied promise of a pardon. This expedient also failing, it was next suggested that the whole affair might be got over, if the officers of the Neptune would depose, that they had seen a sailor carrying a bamboo stick over his shoulder, against which, in the hurry and confusion, a Chinese had accidentally struck his head. This ridiculous proposal being treated with deserved contempt, it was next proposed, that one of the sailors should be prevailed upon to state, that finding an attempt made upon his pocket, he had struck behind him, and might thus have wounded the deceased. Still meeting with no better success, they proceeded in their examination, and dismissed all the seamen except two, Julius Cæsar, and Edward Sheen. It appeared, that Julius Cæsar had a small cane in his hand on the day of riot, but was not on the outside of the factory; and that Edward Sheen was on the outside of the factory, but did not carry a stick. He confessed, however, that he had a Chinese tobacco pipe in his hand, the tube of which was of bamboo; and the court therefore decided, that he carried a stick, and consequently was the culprit. A long negociation then took place as to the disposal of Edward Sheen, till the final decision upon the case should be received from Pekin; and it was at length agreed, that he should be left behind in charge of the supercargoes. The following is the representation, which was made of the case to the supreme court at Pekin, and its decision upon the matter. The viceroy of Canton states, for the information of the supreme court, that Edward Sheen, an Englishman, being in an upper story of a warehouse, which overlooked the street, and in which there was a window opening with wooden shutters, did, on the 18th day of the 1st moon, employ a wooden stick in an oblique direction to keep open the shutter, and that, in doing this, the wooden stick slipped and fell downwards; that *Leao-a-teng* a Chinese, passing at the moment, was struck and wounded by the falling of the said stick upon his left temple; and that, on the evening of the following day, he died in consequence of the wound; that repeated orders had been given to the chief of the British factory to deliver up the man to justice; that in reply it was alleged, the said criminal was sick of an ague and fever, and under medical treatment; that, on his recovery, he was confronted with the relations of the deceased; that, after repeated examinations, the said Edward Sheen had acknowledged the truth of all the facts here stated, without reservation; that he had consequently been proved guilty of accidental homicide, and ought therefore to be sentenced to pay the usual fine, to redeem himself from the punishment of death by strangulation. Upon this report, the supreme court observes, "that the case appears to be one of those acts, of the consequence of which neither sight, hearing, nor reflection, could have given a previous warning; that the said Edward Sheen should therefore

Laws.

be allowed to redeem himself from the punishment of death by strangulation, by the payment of a fine (amounting to about L. 4, 3s.) to the relations of the deceased, to defray the expences of burial, and then be dismissed to be governed in an orderly manner in his own country." This gross fabrication of a story, in mockery of justice, the acquiescence of the different parties interested in the business, and the promulgation of such falsehoods in the face of thousands, who could have contradicted them, was all procured at the expence of the security-merchant, by the division of a bribe of nearly L. 50,000.

Revenue.

The revenues of the Chinese government have been very variously stated by different authors: and, as the natives are all possessed with a most extravagant idea of the greatness of their country, they communicate to strangers their own wide conjectures rather than exact statements on the subject. Hence an inquirer generally receives as many different accounts, as he consults different persons. According to a rough sketch of the sums raised in each province, communicated to Lord Macartney by a Chinese minister, the total annual amount is about sixty millions sterling, of which, after defraying the ordinary civil and military expences, about twelve millions are supposed to remain for the emperor's private establishment. But, as it was clearly the great object of the Chinese rulers to impress the British embassy with the most exalted notion of the strength and resources of their empire, these accounts may be imagined to have been considerably exaggerated. The calculations of M. De Guignes scarcely amount to one half of the Chinese statements to Lord Macartney; and he considers it as next to impossible to ascertain the exact truth on this subject, because the Chinese contradict one another even in their own expositions of the matter, because they are all inclined to exaggerate in their accounts to foreigners, and because, even in writing for the information of their own countrymen, they dare not advance any conjectures or details, which would be prejudicial to the credit of the mandarins, whose honour and interest depend upon the real or pretended prosperity of the empire.

The revenues formerly arose from a capitation tax, which was changed by the emperor Yong-tching into a land-tax with respect to the proprietors or cultivators of the soil; while it appears that the merchants, artizans, and others not employed in husbandry, are subject to a similar assessment upon their shops or warehouses. The land tax is one-tenth of the produce, or rather of the profit, after deducting the expences of cultivation. The lands are carefully registered, and their fertility estimated. Great precautions are used, that neither the occupant be overcharged, nor the government defrauded; and in those districts which have severely suffered from drought or inundations, the emperor, if in any degree desirous of popularity, generally remits the public burdens. In the rice districts of the south, especially the provinces of Quang tong and Quang-see, there is a second tenth raised upon rice, because two crops of that grain are produced in one season. There is farther an excise upon salt, coal, and almost every kind of merchandise; and a duty upon the manufacture of silks and other stuffs. The regulations on this branch of the revenue bear a most striking resemblance to those of Europe; and there is in China a system of permits, excise-officers, licenses to traders, and penalties upon smugglers, almost exactly the same as what is practised in Great Britain. The taxes in general, as far as they affect the great body of the people, may be considered as extremely moderate; and it has been calculated, that, exclusive of the husbandmen, the other classes of the community are not assessed with more than four shillings each. For the collecting of these revenues there are assessors and valuators in every district, who are responsible for its quota in land produce; receivers of the duties upon shops, &c. in the cities; and custom-houses, with their proper officers, in every principal town. At these custom-houses, no interruption is given to travellers for the purpose of searching their baggage and requiring a fee, except at Wampoo and Canton, where the custom-house officers are said to be most irritating and insolent in their investigations of every foreigner's effects. The merchant pays the duties by the piece or weight; and in the former case, the collectors generally depend upon the statements given in his own books. The land-tax is paid partly in kind and partly in money, in the proportion of nearly one half in each. The amount collected in villages and towns is conveyed to cities of the third class; the amount of these to cities of the second; and the amount of these again to cities of the first. From the revenues of each province the civil and military officers are paid in the first instance, chiefly in kind; a certain portion is then reserved, in the public granaries of each city or district, for incidental expences; and the surplus is either transported in kind, or sold for money, which is remitted to the imperial treasury at Pekin, for the use of the court and the establishments of the emperor. A statement of what is collected in the several provinces, of what is reserved in the different cities, and of what is paid into the treasury, is laid before the tribunal of finances, which revises the whole, and keeps an account of all that is expended. Besides these ordinary revenues, additional assessments are sometimes levied, especially in cases of insurrection, when the neighbouring provinces are generally required to contribute the expences of its suppression.

The surplus of the general revenue, after all the expences of the state have been defrayed, belongs to the emperor, who may indeed appropriate to himself what portion he pleases; but it is understood to be usually deposited in the national treasury, as a fund for defraying any extraordinary expenditure, without imposing farther assessments upon the people. The emperor always receives from the general stock, the necessary quantity of rice and other provisions, of silk and other articles, for his household and attendants, consisting of mandarins, eunuchs, servants of the palace, and Tartar bands, who are calculated altogether at a number not less than 100,000. Besides what he may draw for this purpose from the general revenues, his privy purse is supplied by the whole profit of the trade in Ginseng, confiscations, seizures, presents from the principal mandarins, and patriotic gifts from his subjects, in porcelain, tea, silks, &c. which are all pompously proclaimed in the Pekin Gazette, and which afterwards serve as presents to foreign ambassadors and favourites. The emperor possesses also very extensive domains, along that part of the great wall, which is nearest to the metropolis, the rents or produce of which belong wholly to himself and his family; and, besides these lands, he maintains large flocks and herds beyond the great wall, in the regions of Tartary, which are all converted into money for his use. The amount of his private revenue from these different sources cannot be exactly ascertained, but has been estimated at 100,000,000 of French livres, or about L. 4,444,444 sterling. The following view of the gross sum of the revenues and expences of the Chinese government is founded upon the calculations of M. De Guignes; into the grounds of which, however, we have not room to enter, but present our readers merely with the general results.

Revenues.

	French livres.	Sterling
One half of the land-tax in money, according to an Imperial edict in 1777	206,955,000	
Value of the other half collected in kind	206,955,000	
Additional land-tax upon the southern rice districts	161,320,000	
Duties upon salt, coal, &c.	48,047,670	
Duties upon silk and other manufactures	50,722,330	
Capitation tax upon merchants, artisans, &c.	30,000,000	
Duties upon foreign trade at Canton	6,000,000	
	710,000,000 or	£31,555,554

Expenditure.

	French livres.	
Salaries of mandarins civil and military, whether superior or subordinate	57,500,000	
Expence of 600,000 infantry, at 3 taels per month, one half money, and the other half provisions	162,000,000	
Expence of 242,000 cavalry at 4 taels per month	87,120,000	
Expence of the waste of horses, in the proportion of one for every ten, at 20 taels each	3,630,000	
Uniforms for 842,000 soldiers, at 4 taels each	25,260,000	
Arms, &c. for 842,000 soldiers, at one tael each	6,315,000	
Marine, and boats	100,000,000	
Canals	30,000,000	
Forts and artillery	28,175,000	
	500,000,000 or	£22,222,221

	French livres.	
Amount of revenues	710,000,000 or	£31,555,555
Amount of expenditure	500,000,000 or	£22 222 222
Surplus	210,000,000 or	£9,333,333

This surplus is deposited in the public treasury after the emperor has taken from it what he finds necessary, or thinks proper for his own expences. But, though he possesses also a revenue of his own, calculated at 100,000,000 French livres or £4,444,444 sterling, yet it would not seem, that he has much wealth at command; as it appears, that he was recently under the necessity of accepting an offering of 500,000 taels or ounces of silver, £166,666 sterling, from the salt merchants of Canton, and of selling a quantity of his precious stones, in order to defray the unexpected charges occasioned to the government, by an insurrection in the western provinces.

ARMY.

Amount of forces.

According to the statements of the Chinese government to Lord Macartney, the amount of their standing army, even in times of peace, is immense, namely, one million of infantry, and eight hundred thousand cavalry; and, according to a calculation made by his lordship, from the information of the officers, the annual pay and expences of this force could not be less than L. 49,982,933 sterling. These statements, however, M. De Guignes positively affirms to have been greatly exaggerated by the Chinese mandarins, in order to give the embassy a higher idea of their power; and in this view, he adds, that the number of military seen by the British in the different places through which they passed, had been purposely collected from a distance, and placed upon their route. The Dutch embassy, which he accompanied, perceived nothing in the whole of their progress, which served to indicate such a multitude of soldiery. They never met upon their route a single corps, either of infantry or cavalry, in motion. They found only about 40 soldiers at the entrance of cities of the third class, about 200 in those of the second, and from 1000 to 2000 in those of the first. Even at Pekin they saw only two miserable companies of guards at the gates of the palace, a few of the emperor's guards in his gardens of Yuen-ming-yuen, and a small number of soldiers on the day of their last audience. M. Van Braam expressly declares, that he never saw, in all his progress through the capital, more than a guard of six soldiers together; and, during his visit, he did not observe a regular guard even at the gate of the palace. "We passed, and halted," says M. De Guignes, "in the same places as the English; but the number of soldiers, stationed on purpose on their line of progress, was no where seen by us. Every one had returned to his post, and we found only the ordinary number." According to the calculations of different missionaries, the whole of the forces throughout the empire do not exceed 800,000; and the Chinese assured M. De Guignes, that there was not more than 20,000 or 25,000 troops in each province. Upon these grounds, he calculates the whole of the Chinese standing army at 842,000 men, of which number 240,000 are cavalry.

Condition of the soldiery.

As the empire of China enjoys a state of profound peace with its neighbours, of whom there is none sufficiently powerful to endanger its repose, the condition of a soldier in this country is not attended with much danger or fatigue, and is generally very much desired by the natives. Those who enlist are enrolled in the provinces where they are born, or reside; and the corps, to which they are attached, never change their station. Hence the greater part of the army is a kind of fixed militia, never moved from their homes, and even rarely called into service. All the Tartars are considered as soldiers from their birth, and begin very early to receive pay. The father of a numerous family, an only son, or the son of an aged widow, are exempted from military service, except in cases of urgent necessity. Every soldier has his own house, and a small garden, where he lives with his family, and is free to employ himself at any trade when not upon duty, or at drill. Those who are employed at the different stations upon the rivers and high-ways, have generally also a portion of land, which they have leisure to cultivate for their support, and pay their taxes from the produce, like other husbandmen. The greater part of the Tartar cavalry are stationed on the northern frontiers, and in the conquered provinces of Tartary; and the Tartar infantry are distributed in garrisons throughout the different cities of the empire. The rest of the army is dispersed among the smaller towns and villages, where they act as jailors, constables, thief-takers, subordinate collectors of taxes, guards of the public granaries, and in various other offices under the magistrates of police. A great proportion is employed at the military posts upon the high-ways, canals, &c. where they serve both as guards to prevent robberies or suppress disputes, and also as couriers, to convey the public dispatches to or from the metropolis. It is said, that few of the Chinese enter the army, except those who want ability to succeed in the civil department; and the best recruits are procured from the northern provinces.

Pay.

The pay of the infantry, including the price of their rations, according to Mr Barrow, is two taels of fine silver, about 12s 6d. per month, which may amount to 2½d. and a measure of rice, a day; but M. De Guignes makes it three taels, or 18s. 6d. per month; and that of the cavalry, according to both of these authors, is four taels, or 25s. per month. In time of war, every soldier, besides his ordinary allowance, receives six months pay advance; and a part of his regular pay is retained by government, for the support of his family during his absence.

Uniform.

The clothing of the soldier varies in the different provinces, but consists chiefly of large blue jackets edged with red, or brown edged with yellow. Some wear long pantaloons, some breeches with stockings of cotton cloth, and some quilted petticoats with sattin boots. Their heads are covered with helmets of leather, or gilt pasteboard, resembling an inverted funnel, with a long pipe, terminating in a kind of spear, at the top of which is a tuft of long scarlet-coloured hair. These caps, or helmets, have large flaps on each side, which cover the cheeks, and rest upon the shoulders, and are tied with ribbands under the chin. Sometimes these helmets are made of polished iron, and above two pounds in weight. In some provinces, the bowmen particularly wear a kind of cuirass, or coat of mail, made of brown or blue cloth, stuffed with a kind of felt, or with doublings of cloth studded with round brass knobs, each rivetted on the inside upon a small bit of leather. These are sufficient to resist the stroke of an arrow, but not a musket-ball.

Arms.

Their offensive weapons are, swords or sabres, pikes, muskets, bows and arrows. The swords, or sabres, (which they seldom wear except when on duty, and instead of which, those who act as policemen carry whips,) are worn on the left, and not on the right side, as has been supposed, with the point turned forwards in time of peace, and backwards in time of war. A corps, called Tygers of War, use long swords, and large shields of basket-work, on which are painted the faces of some monstrous looking animals, with a view to intimidate the foe. These bucklers are fully two feet in diameter, and weigh about four or five pounds.

Their match-locks, which they generally prefer to firelocks, (perhaps owing to their bad powder, and want of proper steel for making locks,) are mounted on a stock of wood, with a very small but-end; and have generally a kind of fork attached to them, upon which they rest the piece when firing. Each soldier has a black cloth pouch, painted with oil, for containing the balls, a large horn for the powder, a smaller one full of a finer sort for priming, and a small leather bag, or sack, at his arm filled with matches.

The bow is their favourite weapon, and they use it with considerable dexterity, though in a very ungraceful position. The calculate the power of the bow, by the weight which would be required to stretch it. Thus they speak of a bow of 60 or 70 pounds; and the weakest, employed in the army, are of 50 pounds, while the ordinary power is 80 pounds, or sometimes even 100. The archers wear a ring of horn on their thumb, with which they hold the string, while adjusting the bow; and the officers have this ring made of agate, which they keep in a round box attached to their girdle.

Their arrows, of which they have several rows in their quivers, are of different forms. The most singular are those, which have the iron head formed with small hooks; and those, which have it pierced with holes, by means of which they shoot letters into the ranks of the enemy, and thus carry on a correspondence with those whom they may have secured in their interest.

Their tents are made of coarse white linen, lined with blue cloth of the same stuff. They rest upon a wooden frame about 14 feet in length and 5½ in height; are fastened down all around with cords and stakes; and open at each extremity like the folds of a door. Each contains five soldiers, with two men, whose business it is to erect and pack them up. Some of them are round and covered with thick grey felt, but these, though much used by the Tartars, are too hot and dusty.

The Tartars are chiefly armed with bows and long swords; and their cavalry seldom carry more than a sabre. Their saddles are very soft, covered with cloth, and raised very high both behind and before; and their stirrups are so very short, as to make the knees of the rider almost touch his breast, which gives them a very ungraceful appearance on horseback. Their horses are small, and of a poor figure; but are tolerably active, and charge with considerable speed.

The troops are assembled for exercise and inspection at every new moon. They are said to march in a very tumultuous manner, but to perform their evolutions, and to handle their arms, with considerable dexterity. They are drawn up in lines, with the interval of a man's breadth between one soldier and another; and when those in the first line have discharged their pieces, they pass to the rear to reload, which is in like manner done by all the other lines in succession. They are distributed into companies of 25 men, each of which has a triangular standard about six feet in height; and every fifth and tenth man has a small flag, which is fixed upon a short staff at the back of his jacket. The flags and standards of the Chinese troops are generally green; but those of the Tartars are of various colours, white, yellow, red, and blue, or yellow with red fringes, white with red fringes, red with white fringes, and blue with red fringes. Every officer and soldier also, has a small stripe of silk fixed to the back of his coat, of the same colour as the flag of his company, with his name and rank written upon it.

Besides all these accoutrements, which are far from giving them a martial air, every soldier is furnished with a fan, or umbrella; and they are said to have altogether a very clumsy and effeminate appearance. The children of the emperor, and every Tartar of distinction, even to the lowest officer, are required to accustom themselves to the management of a horse, the use of the bow, and the practice of the elementary manœuvres. These Tartar cavalry display a good degree of military spirit; and, together with the troops of the northern provinces, form the bravest part of the Chinese army. The greater part, however, of the soldiery of both nations are represented as extremely deficient in the most essential military qualities, and as indebted, for their conquests over their neighbours, to their own superior numbers, and the unwarlike character of their adversaries. The Chinese troops, particularly, were so despised by the Tartars, when they took possession of the empire, that it became a common saying, "the neighing of a Tartar horse puts the whole Chinese cavalry to flight." Great honours and rewards are lavished upon the troops in time of war. An exact journal is kept of every military transaction; and those, who have displayed superior courage or skill, are particularly mentioned. Those, who signalize themselves in battle, are sure of promotion if they survive; and, if they fall, the rewards, to which they would have been entitled, are conferred upon their families and relations. Even the common soldier, who dies in defence of his country, is mentioned by name in the Gazette; and his hair, bow, and sabre, are transmitted to his family to be interred in the sepulchre of his ancestors.

Gunpowder. It has been supposed, that the Chinese were acquainted with the use of gunpowder long before the Christian æra; and it is not improbable, that this invention was known in China, before it was employed in Europe. It has been considered as highly probable, that the deflagration of nitre may have first been observed in those countries, where it is spontaneously and abundantly produced, as in the elevated desarts of Tartary and Thibet, and in the low extended plains of India and China; and it seems to be admitted as a fact, that fire arms, at least, were used by the Asiatics in war, at an earlier period than they were known by the Europeans. All this, however, is not founded upon very sufficient grounds; and there are many circumstances, which render it very questionable, whether the Chinese were acquainted with the use of gunpowder and artillery, at a period so very remote. If they have been in the habit of making gunpowder since the Christian æra, it must be allowed, at least, that their improvement in such processes is extremely slow, as that which they produce is miserably bad, and is prepared by every individual for himself. There is no public manufacture of the article, and there does not seem to be any uniform proportion observed in the different ingredients. Mr. Barrow states the usual proportion as consisting of one pound of sulphur, and one pound of charcoal, with two pounds of nitre. According to receipts received from the Chinese by the missionaries, there are three pounds of sulphur, and three pounds of charcoal added to eight pounds of nitre; and, according to another, there is only one pound of sulphur and one pound of charcoal put to five pounds of nitre. They use the nitre also in a very impure state, which makes the powder attract moisture very readily, so as to become unfit for use; and they have no mode of granulating the paste, in consequence of which the powder often cakes into a solid mass.

Fire arms. As far as their own annals bear, there is no appearance of their having made early or very frequent use of gunpowder in war. The missionaries admit, that, until the 16th century, few of the Chinese warriors understood the use of fire arms, and that Kong-ming is almost the only one, who employed them, about the year of Christ 200. It is related, however, that, when the emperor Hoay tsong had assembled his council in 1640, a mandarin proposed that the missionary, Father Adam Schaal, should be requested to provide them with cast-iron cannon; but, that another opposed the measure with this assertion, that before the dynasties of Tang (A. D. 619,) and Song (A. D. 960,) they had never heard of fire arms; and that, since that time, any attempt to use them had been attended with bad effects. In other passages of the Chinese records, where fire-arms are mentioned, there is no evidence that artillery is meant by that expression; on the contrary, it is often explained by those very historians who employ it, as implying merely burning arrows, balls of fire, and a kind of *balista* for throwing stones. It is said, indeed, that in 1232, the Moguls, in besieging Kay-fong-foo the capital of Honan, made use of cannons called Tchin-tien-looy, (i. e. thunder making the heavens to tremble) formed of a tube of hollow iron, filled with powder; but another kind of Mogul artillery is described, of which the thunder would not be very formidable, and which consisted of ribs of bamboo joined together, and strongly bound with ropes. In imitation of these, the first Chinese cannon were made of three or four bars of hammered iron joined together with hoops of the same metal; and about 100 of these guns were seen by Mr Bell of Antermony in one of the towers towards the extremity of the great wall, when he visited China in the suite of the Russian embassy in 1720. But, however early, or in whatever form, the Chinese may be supposed to have employed artillery in warlike operations, it is certain that they were never in very general use, and that they were at length entirely abandoned. The missionaries, who entered China about the end of the 16th century, agree, that they saw some bombards at Nankin, but that the Chinese could not use them. In the year 1621, when the Portuguese presented three pieces of artillery to the emperor, it was found necessary to send, at the same time, men who could load and fire them, as there was not a Chinese who knew how to manage them. After being tried at Pekin, these pieces were sent to the frontiers to be placed upon the great wall; and are said to have been found so serviceable against the Tartars, that, by the advice of the military mandarins, and the assistance of the Jesuit missionaries, Schaal and Verbiest, a considerable number were cast for the army; but, notwithstanding all the exertions of these learned men to instruct them in the art, they have made little progress, either in casting or using great guns. The only cannon, which the gentlemen of the British embassy observed in the whole of their progress, were a few ill-formed and disproportionate pieces, near one of the gates of Pekin, lying unmounted upon the ground; a few, of the same description, on the frontiers of the province of Canton; and a small number, apparently 12 pounders, at Hang-tcheoo-foo, with a wooden pent-house over each. M. De Guignes observes, that, except at the last mentioned town, none of the cannon which he saw were placed upon carriages, but upon blocks of stone; that those, on the frontiers of Canton, had the touch-hole of a very large size; and that the balls were made of dried and hardened earth. The Chinese are said to be extremely awkward and timid in the use of the few pieces, which they do possess. In making salutes, they employ three small petards, like pistol barrels, which are stuck erect in the ground, and the soldiers are so afraid in setting fire to these thunderers, that they discharge them by means of a train laid from one to the other. Yet they affect, we are told, the utmost superiority over other nations, even in this branch of the military art; and, when Captain Parish caused a few rounds to be fired, as quickly as possible, from the two field-pieces which the British embassy carried as presents to the emperor, the Chinese officers coolly observed, that their own soldiers could do it just as well, and perhaps better. When Lord Macartney, also, asked the ex-viceroy of Canton, if he would wish to see his guard perform the different European evolutions, he replied with great indifference, that such things could not be new to him, who had been so much engaged in the wars of Tartary, though there was reason to suspect, as Mr Barrow remarks, in relating the circumstance, that the gentleman had never before seen a firelock.

Fortifications.

There are a number of military fortresses, or places of arms, in different parts of the country, especially upon heights, in small islands, or at the confluence of rivers. These are furnished with cannon placed upon masses of stone, not on the top of the wall, but near to the ground, in embrasures shut up with wooden doors, on which are painted the figure of a tiger. The mandarins occasionally visit these forts, when a general salute is fired. The military places exactly resemble fortified cities; and the other forts or walls, constructed on mountains and dangerous situations, are of use only as a check upon robbers. The Chinese cities are all fortified; but their defences consist simply of ramparts, which are generally plain walls, but sometimes are flanked with square towers and surrounded with ditches. These defences are sometimes drawn in a circular, and sometimes in a square form; and are constructed of the earth thrown out of the ditch, lined with stone or bricks; but, in the latter case, there is always a few rows of stones as a foundation for the bricks. They are built in a form sloping towards the summit, but the slope is greater within than without. On the side towards the town, the bricks recede at every row; but, on the outside, the contraction is more gradual, and the bricks are placed without any apparent jutting out of the lower ranges. These walls are always higher than the houses, and are generally from 25 to 30 feet in height, and from 20 to 25 in thickness at the foundation, and from 10 to 12 at the top. The ascent is by a kind of flight of steps, or rather a gently rising road, so as that the mandarins can ride on horseback to the summit. The Chinese make little use of artillery in the defence of their towns or forts; and it has been observed that their walls could not sustain the shock, but would tumble down after a few discharges. Neither could they resist the effects of a bombardment for any length of time; and a moderately sized frigate would be sufficient to level the strongest fortresses on the river of Canton. The point, upon which the Chinese bestow the greatest attention in their fortifications, is the gate, of which there have been observed three different forms of construction, the single, the double, and the triple gate. In the single gate the entrance is strait, opening directly through the principal wall. In the double gate, the entrance is the same as in the single; but there is, in the front, a large earthen mound, surrounded by a wall in the form of a semicircle, and in which there is another opening, sometimes in a line with that in the main wall, and sometimes on one side. The space, or area, between these gates, is used for assembling the guard, and is commonly provided with a few small cannon, laid flat on masses of stone. The triple gate is very rare, and the only one observed by M. De Guignes was in Kin-tcheoo, a city of Shang-tong. In its construction and appearance, it exactly resembles the double gate; but, after passing the second opening, it is necessary to follow the direction of the exterior wall for a considerable space, before reaching the third entrance, which is placed as it were upon a line with the first. The gates have no ornamental building, but are generally formed in the wall like a continued arch or vault. Sometimes small towers are erected above them; and, in these towers, or on the outer circle of the double gates, cannon are occasionally found.

POLICE. Public Calendar.

Among the principal objects of interior administration, or general police, may be mentioned the yearly Calendar, and Pekin Gazette. The former is regarded with the utmost attention, and one is published every year at the emperor's expence. It is composed by the tribunal of mathematics, and is chiefly founded upon judicial astrology. It distinguishes the appointed days, and directs the proper mode of observing the various ceremonies and superstitions, which prevail throughout the empire, and which the government seems to find it useful to encourage.

Public Gazette.

The Gazette is printed daily, or at least every second day, in the form of a small pamphlet, and circulated through every province of China. It contains an account of all the objects of administration, and enters into the most minute details of every measure. It gives the names of the mandarins, who have been raised on account of their merit to posts of eminence; or of those who have been degraded or dismissed, on account of incapacity or misconduct. It gives lists of persons who have been convicted of capital crimes, and of those who have received pardon, &c. It details the calamities which have afflicted any of the provinces, and the relief which has been afforded by government; the various expenditure of the state in supporting troops, conducting public works, or supplying the wants of the people; the liberalities and virtues of the emperor, and the remonstrances which have been presented to him by the superior tribunals, either with regard to public measures, or his own private conduct. Nothing, however, it is to be observed, is inserted in this state paper, which does not proceed immediately from the emperor himself, or which is not submitted to his approbation. Its chief intention is to serve as an organ of government, to impress the people with an idea of the great and unceasing vigilance, which is exerted in promoting their welfare, and of the incomparable excellence of their rulers. Hence it is invested with the character of an infallible document, whose very essence is truth itself; and it is pretended by the government, that instant death would be the sure consequence of any attempt to insert a falsehood in its pages. This, however, merely signifies, that the person who has the management of its publication, would be severely punished, should he presume to insert any article that was not officially communicated from the government; for it is known to contain accounts of measures, which have never been carried into effect; of battles, which never took place; and of victories, which were never gained.

Census of the people.

One of the most ancient and peculiar internal regulations in China, is the enumeration of the people throughout the empire, by families, districts, and provinces, comprehending every individual of every rank, age, and sex. A second register is also kept, of all persons, especially of the lower classes, between 16 and 60 years of age, as the mandarins have power to call upon all who are within that period of life, either for military or civil purposes. These enumerations are made with great precision; and are remarkably useful in enabling the government to know the amount of those, who may perish by earthquakes, inundations, famines, &c.; what supplies may be required in any district, in the event of a scarcity; and what numbers can be furnished for the army.

And of the lands.

There is also a public register of all the lands in the empire, of their fertility and principal productions, both in the view of collecting the tax which the holders pay to government, and of ascertaining the state of agriculture, and the sources of manufactures in the nation.

State of roads.

The Chinese profess to pay great attention to the accommodation and security of travellers, and to the easy conveyance of merchandise; and, by means of canals, they have greatly facilitated the communication between their towns; but they have neglected the construction of good roads, where there is no inland navigation. We are informed, indeed, by some writers, of the excellence of their highways, and of the great care, which is taken to keep them in a state of proper repair. We are told of vallies filled up, and passages cut through the rocks and mountains, to preserve the roads on a proper level; of ways broad and spacious, bordered with trees, and sometimes with walls 8 or 10 feet high, to keep the travellers from encroaching upon the corn fields; of covered seats erected on all the great roads, where the passenger may find rest and shelter; of temples and pagodas by the way side, to which admittance may be always gained during the day; of large and commodious inns, though not supplied either with provisions or beds; of towers, or watch-boxes, erected at certain intervals on the great roads, guarded by soldiers, and furnished with bells and flag-staffs to convey signals. But such accommodations appear to be confined to the neighbourhood of the principal cities; or the Chinese must have different sorts of roads, as they have degrees of ceremony, some of which only they show to strangers, according to circumstances. Mr Barrow expressly assures us, that, in respect of roads, they are inferior to most civilized nations; and that, excepting near the capital, where the middle of the highway was paved to the width of 18 or 20 feet with large stones of granite, from 6 to 16 feet in length, and of proportionable breadth, and at a few places where the junction of the grand canal with navigable rivers is interrupted by mountainous ground, there is scarcely a road in the whole country that can be ranked beyond a foot-path. This assertion, indeed, is directly censured by M. De Guignes, while it is strongly confirmed, even by his own account of the matter. When he sets himself to specify the spacious and excellent roads of China, it is only, as Mr Barrow has said, of those in the neighbourhood of the larger towns, or that leading over a mountain, that he speaks. He admits, that, in the province of Quang-tong, where they chiefly travel by canals, there are only cross-paths to be seen; while he acknowledges in general, that the roads are not so well taken care of as in Europe. He acknowledges farther, that no means are used to preserve or repair those which are made; that the inhabitants are even allowed to encroach upon them with their buildings, so as to narrow the passage extremely; and that open wells are often dug in the middle of the path-way, to the great danger of those who travel during night. Nay, he says, "it is true that they are not commonly paved, and certainly this is a great inconvenience, for, in the rainy season, they are either channelled by the water or covered with clay; and, in the dry weather, they are filled with dust to such a degree, that travellers are obliged, for the protection of their eyes, to wear spectacles set in leather, which sits close to the skin." He finds great comfort, however, in this very circumstance, that in these dusty roads, the carriages rolled so very softly along; thanks heaven, that the Chinese highways were not paved; and prays, for the good of those, who may hereafter travel in that country, that the Chinese may not change their plan, till they have improved their carriages. But, in his anxiety to censure Mr Barrow, he has quite overlooked the additional comfort of these dusty paths, when, in wet and wintry weather, they will be converted into beds of mud; and even forgets the account, which he gives of his own route to Pekin in December, in which he complains of roads six or seven feet wide; of mud so deep, that the bearers of the palanquins could with difficulty get on; and of bridges without parapets, which he often passed in terror. All that the French traveller, in short, (so intelligent in other respects, but so inconsistent with himself on this point,) establishes on the subject, is merely this, that, in most places, he saw *roads marked out* and occasionally *bordered with trees*; but that, excepting in a few instances, scarcely any thing more was done to render them passable. The description given by another gentleman in the same embassy with De Guignes, of their route to Pekin, sufficiently demonstrates, either that they were intentionally conveyed through unfrequented and ruinous roads, or that the state of the highways and their accommodation for travellers is miserably bad. They were carried in bamboo chairs, and frequently obliged to halt during the night in an open uninhabited country, where not a hovel of any kind was to be seen to give them shelter; and even the lodgings, appointed for their reception at the different stages, were generally in such a ruinous condition, as to admit the wind, rain, or snow, on every side. They met with few villages or towns in their route; and many of those which they did find, were falling into total decay. The country, in many places, was covered with water, and the mud hovels melted down by the rain. They often passed over extensive wastes, where there was not a single dwelling, or trace of cultivation, in a space of 8 or 10 English miles; and it was not till they passed the Yellow river, that the marks of wheel-carriages were seen upon the roads, which were so little travelled upon, as to be traced out with difficulty. The rivers in their route had rarely any bridges, and such as were too deep to be forded, were crossed in rafts of bamboo. It is said, however, that the Chinese rulers, though sufficiently negligent in preserving their roads in good repair, are remarkably careful that their subjects shall be at least properly guided on their journey; and that an itinerary of the whole empire, comprehending every road and canal, from the city of Pekin to the most remote quarter of China, is duly published by the authority of government.

Want of inns.

There are no inns in any part of the empire, that is, inhabited houses, where the traveller may procure rest and refreshment; and this want is not compensated by the hospitality of the natives, who are rather inclined to shut their doors against strangers, than to welcome them with the offer of rest or shelter. There are, indeed, what are called inns, or rather resting-places, consisting of bare walls, where the traveller may purchase permission to pass the night, and perhaps procure a cup of tea. Of these there are a sufficient number, some of which are established by government, for the convenience of those, who travel in the service of the emperor; but the officers of the state very generally make use of the temples and convents as places of lodging, when they travel by land; and the infrequency of land-travelling in China is such as scarcely to afford support to houses of proper accommodation for passengers.

Travelling conveyances.

It is scarcely possible to procure horses upon the roads, especially in the southern provinces, but there is no difficulty in finding abundance of palanquins, carts, hand barrows, and especially excellent porters, who are chiefly employed in transporting baggage from one town or stage to another. They are united in bodies in every town under a common chief, who regulates their engagements, fixes the price of their labours, receives their hire, and is responsible for their fidelity. These offices are all regulated by government, and maintain a correspondence with each other. The traveller carries to one of them, before his departure, a list of the articles, which he wishes to have conveyed, and which is immediately entered into a book. Every thing is weighed before the eyes of the chief; the fare is generally paid in advance, at the rate of five-pence per cwt. for one day's carriage; and the traveller, on his arrival at the next city, finds every thing safely lodged at the corresponding office.

Couriers.

There are post-houses established upon the great roads, but solely for the service of government; and no one but the couriers of the state are allowed to use the horses which are found at these stations. These posts or relays are by no means very numerous, and are frequently 80, generally 50, and rarely so little as 40 lee distant from each other. The couriers carry the dispatches in a roll or long bag, covered with yellow silk, and laid across their back; and either the horse has a bell attached to its neck, or the rider strikes upon a copper drum, to announce his arrival, that a fresh horse may be ready without delay. Though the horses, which belong to government, are small, ill-fed, and carelessly treated, these couriers travel at a considerable rate, generally 100, and sometimes even 150, miles in the 24 hours; and they have been known to pass between Canton and Pekin in the space of 11 days. There are also cavalry soldiers at every city, who are intended to carry the orders and dispatches of the mandarins; but who voluntarily take charge of the letters of individuals, which they carry in a leather bag attached to their saddle.

Guard-houses.

Guard-houses, as already noticed, are also placed along the roads for the protection of travellers, at intervals of half a league, a league, two leagues, or even more; and the space between them is commonly marked upon a wooden door in their front. They are provided with a guard of five soldiers, and consist generally of a lodging-house and a stable; sometimes accompanied by a square tower about 20 or 25 feet in height, adorned with parapets, and having a small apartment on the top; or a small wooden cabin, supported by four very tall posts, to which they ascend by a ladder; or a square building of two stories, or a rising ground with a small open room on its summit. These towers, cabins, and heights are used by the soldiers as places from which they occasionally keep a look-out, and make signals to the neighbouring guard stations, by kindling a heap of straw in a brick furnace. The soldiers, however, who ought to do duty at these watch-houses, are frequently absent, and their doors shut. It is only when a mandarin is expected to pass, that they are sure to be at their post; and on such occasions the guard is drawn out, their kettle-drum sounded, and three rounds fired.

Police of the cities.

The gates of the cities are shut during night, and carefully guarded during the day, so that every one, who goes out or comes in, is observed and inspected; and if discovered to be a stranger, or suspected person, is carried before a mandarin, by whom he is detained till the will of the governor be known. There are gates also, or cross bars, at the entrance of every street, which are provided with sentinels, and which are always closed during the night. The cities are divided into districts, each of which is under its own officer; and the house-holders act in turn as constables or tything men, each of whom has ordinarily about ten houses, including his own, under his inspection; and should any riotous company assemble, or any thing contrary to good order take place in his quarter, it is his duty to give information to the nearest watch without delay. Every father of a family is a kind of inspector in his own house, and is responsible for the conduct of all under his roof. Neighbours also are considered as in some degree answerable for each other, and as bound to render mutual assistance in cases of robbery or fire. Patroles go their rounds, striking occasionally as they proceed upon a tube of bamboo, which emits a dull hollow sound; and the sentries mark the watches of the night by means of a bell or drum. Individuals also, whose property might attract robbers, generally place some of their domestics to keep watch, and to shew, by beating upon small sticks, that the whole family is not asleep. All who are found abroad at unseasonable hours are stopped and examined by the watch; and no one is permitted to pass through the streets during night without carrying a light. As the Chinese, however, frequently use in these cases torches of resinous wood instead of lanterns, and as they are extremely careless in the management of these lights, the practice is attended with the greatest danger, and often occasions destructive conflagrations, which the Chinese are as backward in extinguishing as they are negligent in preventing. In these cases the barriers of the cross streets are thrown open, and every one hastens to the spot, some to be spectators, a very few to give assistance, and the greater part to pillage those who are endeavouring to save their effects. Even the mandarins and soldiers use no means to check the progress of the flames, which are generally suffered to rage till there be nothing more to burn; and, though in the suburbs, they are happy to avail themselves on such occasions of the assistance of Europeans; yet, rather than admit them into the interior of a city, they will abandon the houses to complete destruction. Prostitutes are not permitted to reside in the interior of the cities, and have their lodgings in the suburbs, or upon the rivers, where numbers of them are associated together under a male superintendant, who is responsible for their behaviour. But it is not, as has been imagined, from a peculiar sense of decency in the Chinese, that these women are thus excluded from their streets. On the contrary, the boats in which they have their dwellings are to be seen in rows, alongside of each other, where themselves and their frequenters are openly observed by the public; while parties of pleasure are formed on the lakes and rivers by the more wealthy, in barks for that express purpose, on board of which they invite as many of these women as they choose.

Thieves.

Notwithstanding all the precautions and regulations of the police in China, pilferers and robbers are extremely numerous, and are not so readily detected as might be imagined, from the multitude of officers and institutions provided for the public security. Pickpockets abound in Canton, who are very expert in their profession, and generally make their attempts upon strangers. They go in companies along the streets, so that the article stolen is rapidly conveyed from one to another; while some of them are always ready to obstruct the way of the pursuer. They frequently lay forcible hold, even in open day, of the person whom they wish to rob, empty his pockets with wonderful dexterity, and make their escape before he can recover from his surprise. In their nightly depredations, they generally enter houses by the windows, with the aid of a light bamboo ladder, or by making a hole in the wall, in which, that they may easily find it again, they place a small candle made of saw-dust, which gives light without flame; surround the beds of the inhabitants with tables, chairs, &c. in order to obstruct their passage should they awaken and attempt to seize them; and even, it has been affirmed, burn certain drugs in the bedrooms, in order to cast the persons, who are at rest, into a deeper sleep. These bands of pick-pockets and housebreakers are said to have chiefs among them, invested with a certain degree of authority; and by entering into a composition with these persons, it is said that a stolen article may sometimes be recovered. There is not wanting also a more formidable species of banditti, who infest chiefly the sea-coasts and mountainous districts; who murder as well as plunder, and by whom not only defenceless travellers, but even whole villages, are occasionally massacred. These, however, are seldom found in the cities and more populous districts, as every robber apprehended with weapons in his hands is punished with death.

Paupers.

By the laws of China it is enacted, that all poor destitute widowers and widows, the fatherless and childless, the helpless and infirm, shall receive sufficient maintenance and protection from the magistrates of their native city or district, whenever they have neither relations nor connections, upon whom they can depend for support; and that any magistrate, refusing such maintenance and protection, shall be punished with 60 blows. Also, when any such persons are maintained and protected by government, the superintending magistrate and his subordinates, if failing to afford them the legal allowance of food and raiment, shall be punished in proportion to the amount of the deficiency, according to the law against an embezzlement of government stores. But these distributions are extremely rare and limited; and there is no country where paupers and mendicants are found in greater numbers, and in a more wretched condition, than in China. In some districts they are not indeed very frequent, because they could not find subsistence; and either perish of want, or remove to places of greater wealth. Multitudes, who may be regarded in the class of beggars, have no other habitation than a little wretched boat, in which a family of father, mother, and several children, scarcely covered with rags, and of the most meagre and famished appearance, row about the shipping at Wampoo, and procure a subsistence by the charity of the seamen, or by selling the ropes-ends, or other articles of refuse, which they pick up from the river. Numbers are destitute even of these accommodations and resources, and have been seen in the suburbs of Canton crowding together at night, to shelter each other from the cold; many of whom were occasionally found lying dead among the timber and stones upon the quay. "*La pauverté*," says M. De Guignes, who had witnessed such spectacles, "*se montre a la Chine sous des dehors extremement hideux.*" "*Les mendians, qu'on trouve dans les rues de Quanton, font horreur a voir.*" And they are so importunate, he adds, in their petitions, as sometimes to lay hold of those whom they supplicate, and seldom depart without receiving some portion of alms.

LANGUAGE AND LITERATURE.

The Chinese language is so entirely original and unique, in its whole construction, and in its constituent parts, that it may be considered as affording no inconsiderable evidence of the great antiquity of the nation. The subject, till very recently, was but little understood in Europe; and a variety of opinions, or rather conjectures, prevailed among the learned, respecting the origin, progress, and structure of this extraordinary language. From the remarks of Barrow and De Guignes, and especially from the *Dissertation on the Characters and Sounds of the Chinese Language*, by Mr Marshman, one of the Baptist missionaries in India, a more complete and consistent view may be formed of the subject, even by those who have no knowledge of the language itself, than could be collected from the varying and contradictory statements of the earlier writers upon this topic.*

Elementary characters.

The elements of the Chinese language are clearly of a symbolic or hieroglyphic nature; † and its written signs may be described as imitations of natural objects, combined in a variety of forms, in order to convey, or rather to exhibit, ideas to others. The formation of the written characters is extremely simple; and their constituent elements, though variously enumerated in different dictionaries, are, at most, 214 in number. These are called by the Chinese Tsi-moo, or mother characters, and sometimes Poo, or ruling characters; but by the European missionaries they are designated claves, or keys: and by the various combinations of these elementary figures, all the other characters in the language are formed.

Origin of these elements.

The origin of these mother characters is entirely a matter of conjecture; but they may be conceived, as seems to be the general opinion, to have taken their rise from the first rude attempts of men to delineate objects of sight, as a mode of expressing their ideas to others. These representations, or outlines, may be supposed to have been at first very imperfect picturings, and to have lost, by degrees, much of the little resemblance, which they ever possessed to sensible objects. All the Chinese literati consider this to have been the nature of the first endeavours to form a written character; but they are fond of representing the lines of Fo-shee, broken and unbroken, disposed in circles, squares, and polygons, as at once the most ancient of their records, and as a specimen of the original language of their country. They pretend, however, to trace the use of the present characters as far back as the reign of Hoang-tee, about 2700 years before Christ; a period at which, according to their own histories, their nation, if at all in existence, must have been in a very rude and uncivilized state. But whatever may have been the date of the origin of these characters, it appears from inscriptions upon antique seals of agate, vases of porcelain, and cups of serpentine stone, as well as from successive editions of their oldest books, that they bore a considerable resemblance to the objects, which they were intended to represent.

Objects of these symbols.

The individual figures at first selected to form the basis of this mode of communication, include the most remarkable objects of nature, as the sun and moon, a river, a mountain, fire, water, earth, wood, stone, &c.; the principal parts of a house; the utensils most commonly in use, such as a knife, a spoon, a seat, a box, a staff, &c.; the chief articles of subsistence, grain, pulse, flesh, fish, &c.; the primary relations of life, father, mother, son, daughter; some of the most obvious qualities of bodies, such as straightness, crookedness, greatness, smallness, height, &c.; a few of the most common actions of life, such as seeing, speaking, walking, running, &c.

These original elements, of which the other characters, or rather words, are composed, may be regarded as, strictly speaking, the alphabet of the Chinese language.

Prevailing symbols.

They are, however, very irregularly and unequally brought into use in the composition of characters; and, while some of them enter, as roots or primitives, into the formation of 1400 or 1500 characters, others have only two or three descendants. *Mook*, wood, for instance, enters into the composition of 1232 characters; *soi*, water, into 1333; *tchou*, grass, or vegetation in general, into 1423; *shoo*, the hand, into 1012; *kou*, the mouth, into 983; *sin*, the heart, into 956; *nee*, a woman, into 834; *yun*, a man, into 729; *wy*, denoting reptiles, into 804; *gniu*, a word, into 734; *kyam*, or *kyun*, gold, into 719; *see*, silk, or any thing fine and delicate, and *tchok*, a bamboo, into 672 each; *yok*, flesh, *san*, a mountain, *mook*, the eye, *tchok*, the foot, *nieu*, a bud, into somewhat more than 500 each; *ma*, a horse, *khin*, a dog, *yul*, a day, *tou*, a knife, *tchee*, a place, *mic*, me, *tcheek*, motion, into somewhat more than 300 each; and the elements, which represent earth, stone, disease, clothing, and jewels, have above 400 in their respective classes. Thus do thirty of the elementary symbols, expressive of the primary objects of sense, enter into the composition of nearly 20,000 characters; which are supposed to constitute more than one half of the characters in the language. Some of these elements, on the other hand, enter into so few characters, that they are scarcely entitled to be ranked among the primitive figures. The six elementary symbols, which compose the class formed by one stroke, and which are all obsolete, except *yut*, one, include altogether only 95 characters, and one of them has only two derivatives or compounds. Among those which consist of many strokes, there are 40, which comprise in their respective classes not more than 20 characters each, some of these having only 10, and the whole 40 making only 615. Twenty others contain only from 20 to 35 each, and altogether only 557. So that here are 84 of the elements which enter into the composition of only 1427 characters, which is little more than the number classed under the single element of *tchou*, vegetation.

Thus the effective elements amount only to 130, while the rest of the 214 very rarely occur in writing. The whole useful and practical part of the language, also, instead of amounting to 80,000, according to the French missionaries, contains only about 35,000 characters; many of which even are synonimes, and one third of which is more than sufficient for the common purposes of life, and for understanding most of their books. Thus the whole text of the Ta-tsing-leu-lee, or present code of Chinese laws, consisting of 100,000 characters or words, does not contain more than 1860 that are essentially different from each other. The dictionary Shue-ven, composed by Hui-tchee, under Ho-tee, of the Han dynasty, A. D. 89, and the other dictionaries composed after him, contain only between 8000 and 10,000. Additional characters were formed at different periods, and in consequence of changes in the state and relations of the empire; especially when the Chinese became united with the people of the East; when the Bonzes of Fo arrived in the country, a short time after whose establishment, the characters were numbered at 26,430; and when the Tao-tse, imitating the innovations of the rival sect, made new inventions; so that in A. D. 1090, the dictionary presented by Se-ma-kouang to Gin-tsong, contained about 53,165 characters, of which, however, 21,846 are double, to express a different meaning. As the formation of characters, too, by the combination of the 214 elements, is not left to the fancy and pleasure of individuals, but as the sanction of government is requisite to authorise the introduction of a new character into common use; this essential part of the language is completely uniform and stable. Changes may have taken place in the form of the characters, by the removal of redundancies, or the rounding of angles, especially in writing; but the principles upon which they are constructed, continue fixed and invariable; and it is asserted by those who are well acquainted with the subject, that the Chinese language has not borrowed a character or syllable from any existing tongue, or undergone any material alteration in its sound or form, for more than 2000 years. Every new article imported into China, receives an appellation in the language of the country, and soon loses its original name. Even the proper names of foreign countries, nations, and individuals, are translated, or at least converted into others, of a Chinese formation. Thus, Europe is called *See-yang*, the western country, and Japan, *Tang-yang*, the eastern country; Englishmen, *Hung-mou*, red heads, &c.

---

* The latest publication on the subject, of which we have heard, is a Grammar of the Chinese language, published by Mr Morison, a Christian missionary at Canton, and dedicated to Lord Minto, the present governor of Bengal, who, like his predecessor Lord Wellesley, has extended his encouraging patronage to the cultivation of Oriental literature; and whose liberal and enlightened mind is not restrained by the influence of prejudice or party, in estimating the merit of those, who have distinguished themselves in this department.

† This point is well established and illustrated in a treatise by one of the Jesuit missionaries, published at Brussels in 1773, and entitled, *Lettre de Pekin sur le genie de la langue Chinoise, et la nature de leur ecriture symbolique.*

Modes of writing.

With respect, however, to the form of writing the character, the above assertion must be taken with considerable deductions. Previous to that period, which, even by the accounts of the Chinese, is scarcely so remote as 2000 years, various changes were made in the form of writing. 1. The first is called Kho-theoo, which they regard as the most ancient form of writing, and the invention of which they ascribe to Tsang-hie, whom some consider as the same person with Sse-hoang, a prince prior even to Fo-hee, and others as a mandarin under Hoang-tee. He is said to have taken the idea from observing the footsteps of birds upon the sand, and therefore called the characters which he invented Niao-ky-tchouen (*letters imitating the footsteps of birds*); but, as they were supposed to have a resemblance to an animal called Kho-theoo, a kind of water insect, they received and have hitherto borne this last appellation. These are understood to have been the characters in use under the three first dynasties, and not to have exceeded 540 in number. 2. The second, called Ta-tchouen-tse, appeared in the reign of Siuen-vang, about 826 years before Christ, when Shee-tcheoo, president of the historians, arranged the characters under 15 classes, and the emperor caused them to be inscribed upon ten drums, nine of which are said to be still preserved in the imperial college at Pekin. 3. The third, called Siao-tchouen-tse, were new characters composed by Ly-se, the prime minister of Shee-hoang-tee, about 246 before Christ, and founded upon the ancient 540 characters; but the form of these being afterwards changed from crooked to straight lines by Tching-miao, who had assisted Ly-se in composing them, they were called Ly-tse; and new corrections having been made upon the system under Eul-shee-hoang-tee, 206 years before Christ, they were named Kiaee-tchoo. 4. The fourth, called Tsao-tse (*characters of herbs*), were invented under Tchang-hoang-tee, A. D. 80, but as this mode greatly disfigured the characters, it was soon abandoned, and is now used only as a running hand. 5. The fifth and present character, called Hing-shoo, was invented under the Heoo-han, or posterior Han, who reigned from the year of Christ 224 to 264, by a person named Lieoo-te, who, while he preserved the spirit and system of the ancient characters, endeavoured to facilitate the manner of writing them. But he thus deprived them of their resemblance as pictures to the objects which they expressed; and hence these modern characters do not speak so well to the eye, as those formerly in use. Though capable of being more expeditiously written, they require more care in the formation, as a single stroke, more or less, would often alter the signification entirely, while the ancient characters, being a kind of pictures, were in a great measure intelligible, whether well or ill drawn. The Chinese have still various modes of writing the characters, as it is certain that, when the emperor Kien-long ordered his poem of *Mouk-dan* (the name of the capital of Mantchoo, Tartary,) to be written out in all the various kinds of character which had at any time been in use, it was found, that they amounted to the number of thirty-two. The dictionary published by order of the emperor Kang-shee, has now indeed fixed the form of the written character more decidedly; as it is accounted a breach both of good taste and sound loyalty to alter or abbreviate the characters employed in that publication.

Combination of elements.

The knowledge of the elementary characters does not lead, as might be supposed, to a knowledge of the meaning of their combinations; as there frequently exists no affinity whatever between the signification of the compound and its component parts, or at least such a connection only, as is founded more in fancy than in fact, and as could never be discovered by the learner, in consequence of his previous attainments. The constituent parts, indeed, of every compound character, are always distinctly separated, and accurately described in the dictionaries; but it is very seldom, that an explanation of the meaning can be drawn from the import of these elementary materials. The number of the primitive signs is too limited to express a great variety of ideas; and among those which are invented, there is a great want of those leading and general representations, under which a systematic classification of mixed objects and abstract notions might be arranged. Hence, though the plan of the written language may appear well adapted to be the groundwork of a philosophical character, as a universal medium of communication; the theory has been greatly marred by the Chinese in the execution, and their whole language seems to have been formed rather by accident and caprice, than by system and design.

Classification of characters.

The whole characters of the Chinese language are usually arranged, in their own books, under the six following classes, to which they give the name of Lo-tchoo.[*]

1. Siang-hing, i. e. *image and symbol*, or those which give the simple figure of the object, and sign of the idea, comprehending two kinds of characters, first, those which represent, by a visible picture, the objects expressed, as the figure of a vase employed as the character or word for a vase; secondly, those which are either by allegorical signification or arbitrary appointment the signs of intellectual ideas, as the figure of a heart to express love and affection. This class comprehends the elementary symbols.

2. Tchee-sse, i. e. *indication of the object* or idea, or those compound characters which follow the simple and obvious sense of the primitives of which they are composed, and thus give at least some indication of the meaning. Thus the character of *little* combined with

---

[*] The term Lieou-lee, or Lieou-ee, by which some of the missionaries have distinguished these classes, is used by the Chinese to denote rather the six primitive arts of life.

that of *strength*, denotes weakness; the character of *man* written three times signifies a *multitude*; or if they are placed in a line behind each other, it denotes the action of *following*; and the character of *herbs* and *water*, united with that of a *field*, expresses a swamp or marshy soil.

3. Hoey-ye, i. e. *combination of the object* or idea, includes those characters, which convey a sense, bearing no immediate relation to the separate significations of the signs of which they are composed, but which may be found to possess a kind of distant analogy with the ideas expressed. Thus the characters of *mouth* and *dog*, signifying to *bark*; those of a *door* and *mouth*, to *ask a question*; those of a *door* and *ear*, to *hear*; those of a *foot* and *lose*, to *fall*; those of *man* within an *inclosure*, a *prisoner*.

4. Kiai-in, i. e. *explanation by the sound*, includes those characters, which are composed of the character of a genus with another character, which, by its sound or some other peculiarity, or by mere arbitrary appointment, designates a species of that genus; and which thus constitute a classification of objects in natural history, articles of household furniture, &c. Thus the character of fish with another sounding *lee*, denotes a *carp*; that of *bird* with another sounding *go*, signifies a *goose*; that of a *tree* with another sounding *pe*, signifies a *cypress*; or with one sounding *lioo*, signifies a *willow*.

5. Kia-tsié, i. e. *idea borrowed or metaphorical*, includes those characters, which, besides the simple signification of the character itself, have also another meaning of a figurative nature. Thus the character of a *tower* signifies literally a building of that name, and also *immobility*; that of *sun* and *moon* united denotes literally *brilliancy* or *splendor* in a physical sense, and also *noble* or *illustrious* in a moral import; *speech* and a *mountain* denote *boasting*; the *wife of a magistrate* implies farther an *accomplished* lady; a *wild boar* both signifies the animal so called, and also figuratively *courage*. This class is exceedingly numerous, and may indeed be said to comprehend the whole characters of the language, which are all occasionally used in a figurative sense. This application of simple characters in a metaphorical import, is the great source of the obscurity which necessarily pervades Chinese compositions, as the figurative meaning frequently bears no conceivable analogy to the primitive sense, or at least one extremely remote.

6. Tchuan-tchoo, i. e. *extension, developement*, includes those characters, in which the obvious or figurative signification is varied either partially or wholly by another character placed above or below, on the right or the left; but, whether any regular principle is observed in this alteration or extension of the meaning by *juxta position*, does not appear. Thus the character of *mountain* alone signifies a *single mountain*; two of them in a line, *a range of mountains*; and these two surrounded by a third, an *elevated mountain*; a *heart* placed above a *slave* signifies *anger*; an *ear* at the side of a *heart* denotes *modesty* or *shame*; a *man walking* and a *word*, *vain promises*.

Analysis of characters.

To trace the meaning and composition of the different characters is described as a very entertaining analysis and ingenious exercise; as affording also the most curious examples of the operations of the mind in different nations and ages, in combining and associating ideas. The greater part indeed cannot be traced to the circumstances and notions which gave them birth; but it is most probable, that, in many instances, this difficulty arises from a want of acquaintance with the history, customs, manners, sentiments, and traditions of the Chinese nation, to which it is evident that numbers of these combinations have a direct reference. Thus the Emperor Yao and a word signifies *religious discourse*; the same person with the sun denotes *eminent knowledge*; and with provisions, conveys the idea of *nourishing the people*; all these significations evidently alluding to the character ascribed in history to that prince. A bow and the chace express *the nations of the north*; a man and a flock, *those of the west*. Wine and a seal express *marriage*, because it was the custom for the bridegroom to present wine to the bride, which was thus the seal of their union. A garment and a halbert signify a *short coat*, because soldiers usually wore short clothes; old and word *instructive conversation*, because wisdom is supposed, especially in China, to be the character of the aged. Woman and sickness express *death*, because when the sovereign was sick and given up by the physicians, he was left in the hands of the women. A concubine, or second wife, is signified by *girl* and *upright*, because she must stand up, and is not allowed to sit in the presence of her husband. The *intercalary moon*, or month which returns at certain intervals to make the lunar agree with the solar year, is represented by the character *king* in the middle of a *door* or gateway; because it was anciently the custom, at the return of the intercalary month, for the sovereign to stand in the gate of the temple when making his oblations, instead of performing the ceremonies, as on other occasions, within the temple. To govern is compounded of *bamboo* and a *clapping noise*, which sufficiently indicate the great instrument of Chinese administration, the stroke of the bamboo; and the character signifying foreigner is composed of *great* and *bow*, perhaps because the first strangers, who entered the country, carried longer bows than those of the natives.

Sound or pronunciation of the characters.

The Chinese characters are not addressed solely to the eye, but are all capable of being named so as to be in some measure intelligible by the ear. But it cannot be said, properly speaking, that each character has a distinct name or sound. These sounds are very few in number, between 300 and 400 only; and, hence, many characters, essentially distinct in their appearance, have the same name. Even these names, also, are not composed of the names of the component parts of the character; but, however numerous these may be, its own name is always a monosyllable, which generally bears no resemblance to the sounds of its constituents. Thus the character expressing happiness, is composed of four characters, viz. *shee* a dæmon, *ye* one, *koo* a mouth, and *tien* a piece of cultivated ground; but the word or character *happiness* itself, has the simple monosyllabic name or sound of *foo*. Hence it is, that the written Chinese characters, like the notes which compose a piece of music, may be intelligible to different nations, whose spoken language is different, that is, who give different names to the visible words or characters. This is actually the case in Japan, Tonquin, and Cochin-china, where different languages are spoken, but where the same written character, namely that of the Chinese, is used. Indeed it is said that such is the case, even in the empire of China; and that scarcely any two of its provinces pronounce the characters in the same way, or, in other words, have the same oral language.

Chinese alphabet, or marks of sound.

For the purpose of regulating the pronunciation, or names of the characters, the Chinese have a class of characters set apart as marks of sound, which may be called their alphabet; but when, or by whom, these were invented, is not known. This alphabet has a close connection with their imitative character, and is considered as extremely simple and effective. It consists of 36 characters, whose names furnish so many initial consonant sounds; and of twelve other selected characters, whose names furnish as many final sounds. Some of the initial consonants, however, are so much alike, that scarcely more than 24 of them can be considered as admitting of a separate pronunciation. They are distributed into nine classes; and their power is expressed in the following Table, as far as it can be effected by English letters.

1	K.	Kh.	K.	Gn.
2	T.	Th.	T.	Ng.
3	Ch.	Chh.	Ch.	n.
4	P.	Ph.	P.	m.
5	F.	Fh.	F.	m.
6	Ts.	Tsh.	Ts.	S. S.
7	Tch.	Tchh.	Tch.	Sh. Sh.
8	Y.	H.	Y.	Hh.
9	L.	Y.		

This alphabet, according to the conjecture of Mr Marshman, may be conceived to have been formed in the following manner. Suppose the two characters of sun and moon, named *je* and *yue*, united into one to express brilliancy; and this new compound to have been at random named *ming*, a sound without any meaning or reference to the sounds of the component characters. In order to express this sound to another person in writing, as the conventional term for this character, it might be natural to look among the characters already named, especially the elementary symbols, for one or more, whose sounds approached nearest to that of *ming*. Among these the character *moo*, wood, would be found to have the same incipient sound as *ming;* and the character *ching*, blue, the same final sound. Thus might these two characters placed together, convey to another person in writing, an idea of the word *ming*, by uniting the initial of the one with the final sound of the other; and then they might continue to form part of the new alphabet, the one always indicating the sound of m initial, and the other that of *ing* final. The twelve vowel sounds with two nasal in addition, are a, e, i, o, ou, u, an, ang, en, eng, in, ing, oun, oung; and in the Imperial Dictionary, the whole alphabet is explained by twelve tables. The characters, representing initial sounds, are ranged along the head of the page, while those which denote the final sounds, form a column along the margin; and, at the angle, formed by lines drawn from the characters in these two columns, is placed a well known character, which expresses the sound produced by the union of the two, the initial and final sounds. This may be better understood from the following example:

Initial Sounds.

Final Sounds.	P-ong	Ph-ong	M-ing	Ts-ing
K-an	Pan	Phan	Man	Tsan
K-ou	Pou	Phou	Mou	Tsou

Here it is evident, that the initial sound of P-ong united to the final of K-an produces Pan; that the initial of Ph-ong, with the same final of K-an, makes Phan; that the same initials of P-ong and Ph-ong, with the final of K-ou, make Pou and Phou, &c.

Number of syllabic sounds.

In this manner, by the combination of the 36 initial consonants, and the 12 final sounds, are produced and represented 432 simple monosyllabic sounds, which, in fact, form the amount of syllables in the oral language of China. But, as these few syllabic sounds would occasion great ambiguity when distributed among 35,000 different characters, the sounds of the final syllables have been so variously modified, as to increase the original number of syllabic sounds to 846; and these again, by means of certain accents and intonations of the voice, are augmented to 2178.

Accents.

These accents bear some resemblance to those of the Greeks, and are chiefly, four; *Ping*, which signifies *even* and *moderate*, is the common or grave accent; *Siang*, which signifies *ascending*, is the acute accent; *Shee*, which signifies *protracted*, is the long sound or syllable; and *Yu*, which signifies to *stop short*, is the short sound or syllable. In order to mark these accents in writing, the Chinese assign to each of them a particular angle in those characters, which change their meaning according to their accents; the inferior left angle to the accent *ping*; the superior left angle to the accent *siang*; the inferior right angle to the accent *shee*; the superior right angle to the accent *Yu*; and these angles are marked in the school books with an O, frequently of a red colour, to point them out more readily to the notice of the learner. Still, with all the aid which can be derived from these accents and flexions of the voice, the spoken language is full of ambiguities, which, though frequently removed by the general meaning of the discourse, are sometimes perplexing even to the natives. Thus, by dividing 35,000 characters by 2178 syllabic sounds, the number of characters or words, which have precisely the same sound or pronunciation, will be 16 in each class of sounds; and, by dividing by 846, the number of those which have nearly the same sound, will be 41 in each class. In the case of these words, which have the same sound, a second syllable is sometimes added to make the distinction more clear. Thus the syllable *foo*, a name given to several characters of different meanings, denotes a father; and when used in this sense, the word *chin*, kindred, is generally added, as *foo chin*, father. Nothing also is more common, than for the hearer to interrupt the person who speaks, in order to ask an explanation of any ambiguous expression; and this explanation he endeavours to give by adding some synonymous or analogous term. But, with all these resources, a Chinese is frequently unable to make himself understood by his speech; and to explain his meaning, describes in the air with his finger or fan, the figure of the character, whose sound he wishes to utter. All this ambiguity is greatly increased by the obscure manner, in which the Chinese designedly express themselves; affecting to say much in a few words, and omitting, for the sake of elegance, the explanatory phrases.

Dictionaries.

The Chinese dictionaries are arranged, either according to claves, or accents. The dictionaries of the former description have the 214 claves, or elementary symbols, (though sometimes a greater number is used) drawn in a fair and distinct form, along the top of the page, commencing with the more simple, which contain the smallest number of lines or points, and proceeding to the more complicated, in which may be found, at the utmost, seventeen lines. On the margin of the page, are marked the numerals 1, 2, 3, &c. which signify, that the root or element at the top will be found in that page combined with one, two, three, &c. lines, or points. The first step, in examining a dictionary for a particular character, is to find its key or root, which is placed on the right, on the left, at the top, or at the bottom, and which a little practice soon enables the learner to distinguish. The meaning of the character may then, sometimes, be conjectured from the root or key; as the sign of the *hand*, found to be the key of any character, would imply, that it expressed some work of art, trade, or manufacture; or that of the *heart*, some of the passions, affections, or sentiments of the mind. When it is necessary to proceed farther, to ascertain the precise meaning from the dictionary, the next step is to count the number of lines or points in the character, without including those of the key or root; and this is considered as one of the most perplexing exercises to the beginner, as he is apt to reckon those lines, which are merely terminations, or joinings of the different strokes, and which he can learn to distinguish, only by being accustomed to write, as well as to understand the characters. Suppose then the character, for which the dictionary is consulted, to have, as its key, the simple sign expressing *water*, and to contain, besides, six additional lines or points, the scholar turns to the place, where the character water stands, at the top of the page, and looks along the margin, till he find the numerical character six, when he will perceive all the characters in succession, which are formed of the sign of water, with six additional lines. Besides the signification of the character, its name or sound is, at the same time, expressed by the alphabetical signs, already described; as, for instance, to shew the pronunciation of the character *tchong* faithful, there would be found underneath it the words *tchee*, and *loong*, with the term *tsie* to cut or divide, denoting, that the initial *tch* and the final *oong* are to be divided or separated from their respective words, and joined together, to form the sound required, *tchoong*. There are dictionaries also among the Chinese, arranged according to the accents, by which, if the pronunciation of the character is known, the signification may be found; and others, in which the characters are distributed, as in a vocabulary, under different heads, where, if their meaning is known, their name and pronunciation will be found.

Grammar.

In the Chinese spoken language, there is no *b*, *d*, *r*, *x*, or *z*; no word begins with *a* or *e*; and all of them terminate with the vowels, *a*, *e*, *i*, *o*, *u*, *ou*, or the consonants *n*, *ng*, and *l*. The grammatical construction of the language is extremely simple. There is no inflexion of termination; but every character remains the same unchangeable monosyllable, through all its numbers, persons, moods, or tenses; and may be employed as a noun, adjective, or verb, without the smallest variation in its sound or form. The signification is thus determined by expletives or particles, which are frequently omitted in the written language, especially in the more elevated compositions; but which are more numerous in the spoken language, and colloquial style.

Substantives.

In *substantives*, the genitive case is formed by the particles *te*, *tie*, *tche*, placed after the nominative; or, when these are suppressed, by putting the word in regimine before the other, as *kia-tchoo* of the house the master; the dative, by the particles *eu* or *ee* preceding the word; the accusative by its position, which is almost uniformly after the verb; the ablative, by the particles *tung* or *tsung* before the noun; and the plural number is produced by the addition of the syllable *men*, or *mun*, or by some word expressive of quantity or plurality, as *to-jin* many men, or by repeating the noun, as *jin, jin*, men.

Adjectives.

In adjectives, there is no termination to express agreement with the substantive in gender or number; but they are generally placed before the noun. Many adjectives are formed from the genitive of the substantive, as *pai* whiteness, *pai-tie* white, *hau* goodness, *hau-tie* good; but, when united with a noun, the particle is generally omitted, as *hau jin*, a good man. The comparative degree is formed by prefixing the particle *keng keng hau*, better; and the superlative, by repeating the word as *hau-hau* very good, or by adding farther the particle *tie*, as *hau hau-tie*.

Pronouns.

The personal pronouns are *go*, or *ngo*, I; *ne*, thou; *ta*, he; of which the plurals are *ngo-mun*, we; *ne-mun*, you; *ta mun*, they. The sign of the genitive converts these into possessives; as *ngo-tie*, mine; *ne tie*, thine; *ta-tie*, his; *ngo-mun-tie*, ours; *ne-mun-tie*, yours; *ta-mun-tie*, theirs.

Genders.

The genders are sometimes expressed by particles prefixed, as *nan-jin*, a man, *niu-jin*, a woman; but different words are employed in the case of animals, as *kong* a male, and *moo* a female quadruped; *Hiong* or *kio*, a male, and *moo* or *tse* a female bird.

Verbs.

In verbs, there are only three tenses, that can be said to be distinctly marked, the present, the past, and the future, as *ngo-lai*, I come, *ngo-lai-leao*, I come or have come, *ngo-shau-lai*, or *ngo-pee-lai*, I shall or will come, or, when any determined future purpose is expressed, *ngo-yuen-ee-lai*, I am determined to come. The other moods and tenses are marked by particles, adverbs, or even by other verbs; as in the imperative, or at least what corresponds with that mood, it is often said, *Kaee khee*, to open begin. In like manner, a passive signification is expressed by certain particles, such as *shee*, equivalent to is or are, *pee* to was or were, &c.

Syntax.

The syntax is also simple and easy; the nominative generally preceding, and the accusative following the verb. The chief difficulty consists in properly placing the prepositions, adverbs, conjunctions, and other particles, upon the exact position of which the meaning and elegance of the expression often entirely depend. The two negatives *mo* and *poo* are particularly frequent in the spoken language, and have a very extensive use. The first, generally employed along with the verb *yeu*, expresses want, or deficiency, as *mo-yeu-nai*, there is no milk, I have no milk; the latter denotes an opposite quality to the word, which it accompanies, as *hau*, good, *poo-hau*, bad; *je*, hot, *poo je*, cold.

Mode of teaching.

The mode of teaching the written language, as practised among the Chinese, appears to be exceedingly tedious and preposterous. Instead of teaching first the signification of the simple roots, and the analysis of the compound characters; and afterwards, or, at the same time, the sounds or pronunciation; the scholar continues, for five or six years, to learn to name the several characters, without attending to their meaning. He is next employed, for at least four years more, in learning to form the characters, by tracing copies faintly drawn with red ink, and then, by imitating them on fresh paper; in combining the pronunciation with the writing, by naming the lines and points which compose a character, and describing the form and order, in which these lines must be placed, in drawing the character; and in acquiring the difficult talent of following the motions of a person's finger, describing the different characters in the air. Thus a youth, of fourteen or sixteen years of age, is able to write and name a multitude of characters, without knowing the meaning of one. The last step is to analyse the characters by the help of a dictionary, and to understand the use and signification of the written language. In this way, the scholar passes through a regular course of reading and hard study.

Elementary books.

The elementary books are; 1. The Pe-kia-sing, or *proper names of a hundred families*, a book, which contains the various names of individuals in the nation, which are all significant words, and require to be known when found in books, that they may not be mistaken for the names of things; 2. The Tsa-tse or *collection of letters*, a book, which treats of common things, and the necessary articles of life; 3. The Tsien-tse-ooen, or *collection of a thousand letters*, a book which contains 1000 different words, arranged as short phrases of three or four characters; and, 4. The San-tsee-king, or *verses of three syllables*, a book, in which every member of a sentence contains three characters, and which teaches the simplest moral reflections and historical events. They next pass to the Ssee-shoo, or *four books*, containing the moral precepts of Confucius, which they commit to memory, and learn to write out without looking at the book. They are then introduced to the perusal of the *king*, or classical books, of which an account will afterwards be given; and after being exercised in the elevated style of composition, by which time they are generally about twenty years of age, they are to enter upon the first examinations.

Examinations.

These take place in the presence of the governor of a city of the third order, and are generally attended by about 600 students, of which perhaps about 400, who receive the name of Hien-ming, pass to the second examination, before the governor of a city of the first order, when they are employed in producing a piece of literary composition, and in which case, seldom more than 200 are chosen to receive the title of Foo-ming. Before, however, they can be admitted to the higher offices, they must continue to study, and to undergo examinations, for the space of about ten years more. Every three years, a mandarin from Pekin holds two examinations in the chief city of every province; and the Foo-ming, appear before him without books, to prepare their compositions. Of these he is supposed to judge impartially, without knowing the authors, (though money and influence generally prevail) and a small number of the most eminent, perhaps fifteen out of some hundreds of competitors, receive the title of Sieoo-tsai, or bachelors. All, who are admitted into this class, wear a distinguishing badge, and can be punished with the bamboo, only at the judgment of a particular mandarin, to whom the inspection of their conduct belongs. But, as they must continue to produce compositions at the examinations, in order to preserve this degree; the greater number of candidates purchase, at the rate of £100 sterling, the title of Kien-song, which, though attended with less honour, is also attended with less labour, than that of Sieoo-tsai. Both these classes, repair every three years, to the capital of their province, where they compete, by their compositions, for the title of Kiu-jin; and, the following year, all the Kiu-jin, from the different provinces, are required to attend an examination at Pekin, which takes place every three years, and at which the most advanced receive the title of Tsin-tse, or doctors. Those who attain this rank in learning, are eligible to the most important offices in the empire; but the greater part of the literati remain satisfied with the title of Kiu-jin, which is sufficient to obtain for them very honourable stations. This course of study is not pursued in China so much from a love of learning as of place; and a learned man, without wealth or office, is not held in great estimation. These degrees also are frequently purchased; the sons of the higher mandarins are admitted to offices of eminence, without any examinations or degrees; and it is not uncommon to find the governor of a city a mere military mandarin, without any literary acquirements, and assisted in his duties by inferior civil officers. These examinations are restricted merely to a knowledge of the language. Each candidate is provided with pencils, ink, and paper, in a separate apartment, and produces a theme upon a given subject in a given time. The excellence of the composition consists in these points, that the characters be neatly and accurately made; that they be well chosen, and not those which are in vulgar use; and that none of them occur twice in the same composition.

Styles of composition.

There is a variety of styles, or modes of composition, in the Chinese language:

1. The Koo-ooen, or the style of the books named *King;* and which is subdivided into three kinds, one extremely concise and full of metaphors, which is the style of the *King;* a second is that of the books composed after the *King*, till the destruction of the Chinese books by Shee-hoang-tee, 213 years before Christ; and a third is the style of the books, produced from the dynasty of the Han until that of the Song. The two last bear a great resemblance to the first, and can be distinguished only, as connoisseurs distinguish an original painting, of some celebrated master from a copy, taken by a skilful hand.

2. The Ooen-tchang, or the style of elevated compositions, which is not so laconic as the Koo-ooen, but is even still more flowery and recondite. In this style, a writer is expected to choose such characters, as at once give ornament, meaning, and vigour to his sentiment. In speaking, for instance, of the death of the emperor, instead of using the ordinary word Sse, *to die*, he would employ the term Pin-tien, *a guest has entered into heaven;* or, what would be still more emphatic and sublime, the word Pong, *a mountain is burst and tumbled in pieces.* Neither must the same sound frequently recur in the perusal of the piece; a circumstance, which, owing to the small number of sounds in the language, it is most difficult to avoid. To compose, in short, in this style, requires the greatest care and knowledge; and is a very rare attainment.

3. The Kooan-hoa, which is the style employed by the mandarins, the literati, and all well educated persons, is much more extended than the last mentioned; admits of synonymes, and all those connecting particles which give clearness to the discourse; and allows the words to be arranged in a more simple and natural order; but cannot be employed so well in writing, and serves only for oral communications.

4. The Hiang-tan, which is only a corruption of the former, is the ordinary dialect of the populace, and varies in the different provinces and districts. Persons of education are able to speak in the common style of their native place, but never employ it in conversation with mandarins or learned men.

Punctuation.

The Chinese make no use of punctuation to distinguish the conclusion of their sentences; a circumstance which greatly increases the obscurity of their compositions, especially in the elevated style. Sometimes in their commentaries, and especially in the Chinese books published by the missionaries,* the mark O is introduced to point out the termination of a sentence. The Chinese authors follow as closely as possible the style and manner of their ancient writers; and as these never

---

* These publications are considered as the best adapted for learners of the language; especially a small theological treatise, entitled, Ooan, ooe, tchin, iooen, or, *the true origin of all things.*

Language.

employed any kind of punctuation, it would discredit a modern author, and almost infallibly expose his pieces to condemnation, were they disfigured by the useful but vulgar invention of points.

Stability of the language.

In consequence of this faithful adherence to the ancients, the language has undergone no radical change, since the days of Confucius, whose style and manner differ very little from those of the best modern Chinese productions, except that these latter are seldom so concise; and there is still extant a dictionary, entitled See-ooen, compiled under the dynasty of Han, about 2000 years old, which is still considered as of high authority. The Chinese seem to cherish a kind of sacred reverence for their written character; and it is accounted not merely a want of taste, but even a positive misdemeanour, to tear a written paper, and throw away the fragments. Every scrap of writing is carefully picked up, and put into a small pouch, or hollow bamboo, which every man of letters carries about with him for the purpose. The circumstance of a language, spoken by so large a portion of the human race, continuing during such a length of time without any material change, has been considered as a striking confirmation of the observation of Dr Johnson, in the preface to his Dictionary, that "the language most likely to continue long without alteration, would be that of a nation raised a little, and but a little, above barbarity, secluded from strangers, and totally employed in procuring the conveniences of life."

Literature.

There is still very little known in Europe of the state of literature in China, and of the contents of their various writings. Their books are distributed into four classes; 1. The sacred, or canonical books, which comprehend every thing relating to the study of the language; 2. The writings of the historians; 3. Those of the philosophers; and, 4. The miscellanies, or poetry, eloquence, &c. Of these, the most esteemed, and the most studied, but at the same time the least understood, are the few books, or rather fragments, which are supposed to have escaped the conflagration of Shee-hoang-tee, and which are distinguished by the name of *King*. These are generally reckoned five in number, though the three first only are considered by many of the Chinese as properly entitled to the name.

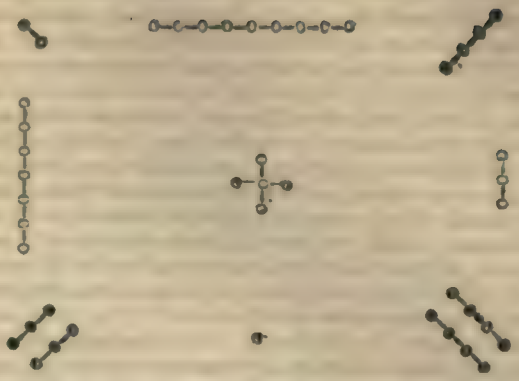
[illegible]

1. Y-king, or the explanation of the lines of Fo shee. These lines are supposed to be the most ancient piece of Chinese writing, and are ascribed to the pen of Fo-shee, who is said to have observed them upon the back of a dragon; and are regarded, most absurdly, by many Chinese, as the basis of their written character. They are called Kooa, and are supposed to contain the principles of all things that exist, the formation of the universe, and the whole system of nature. The emperor Ven-vang attempted, by short notes, to give some explanation of this philosophical enigma, increasing the number of kooa from 8 to 64; his son Tcheoo-kang added a more ample interpretation; Confucius at length published a commentary, both upon the lines themselves, and upon the notes of the two emperors; and these several pieces form the contents of the Y-king. These lines seem, after all to be utterly incomprehensible, and to admit of no better interpretation than that of Mr Barrow, who considers them as nothing else than the school-boy's amusement of the magic square, in which the nine figures are arranged in such a manner as to make the number 15 in whatever way they are added.

This view of them may be rendered more intelligible by the following diagram from that author:—

Literature.

Lines of Foshee.



2. The Shoo-king, a collection of historical records of the earliest sovereigns of China, arranged and edited by Confucius; a book, which is regarded as divine, and the characters of which are all numbered; which teaches the strictest stoical morality, and which is the basis of the government and laws of China; which inculcates, under the form of history, the reciprocal duties of the prince and people, and the perusal of which is accounted the most improving study for the emperor and his ministers.

3. Shee-king, a collection of odes, and maxims, but so full of obscure metaphor, as to render a translation very difficult and uncertain.

4. Lee-kee, or a compilation of laws, ceremonies, usages, and maxims of Confucius, collected by the disciples of that philosopher.

5. Tchun-tsieoo, consists chiefly of annals of the kingdom of *Loo*, composed by Confucius.

There is also another class of books called King, of an inferior order.

1. The See-shoo, or four books of Confucius, called Ta-hio, or *sublime science;* Tchong-yong, or *just medium*; Lun-yu, or *words and discourses*, and the works of the philosopher Meng-tse.

2. Two books upon the rites of the dynasty of Tcheoo.

3. Books on filial piety, and certain poetical compositions, entitled Tsoo-tse, and Shan-hay-king.

4. The three ancient commentaries upon the book of Tchun-tsieoo.

5. The works of the historian Se-ma-tsien, and of some other authors.

Translations of Chinese works.

The greater part of the *King* have been translated and published in France by the Jesuit missionaries. But their translations are censured by those who are skilled in the subject, as having too much of the European character and style engrafted upon the Chinese originals, and as neither conveying an accurate idea of the original, nor a certain transcript of the meaning. As far as can be judged from the portion of these books which is intelligible, they impart very little knowledge either of the ancient or modern state of China.

Among the principal Chinese productions which are known in Europe may be mentioned the Ta tsing hoei-tien, which contains a compendium of the existing laws, with all the forms and regulations of the several departments of the state; of the rites and ceremonies of the empire, the administration of justice, the system of revenue and finance, &c. and which would afford, it is supposed, the most important information respecting the state and government of China; the Tay-tsing-ee-tung-tse, a complete Encyclopædia of arts and sciences, extending to 200 volumes, and published by the authority of the Emperor Kien-long; the Tong-kien-kang-moo, a general history of China, translated into French by Father Mailla, in 14 volumes; the Hao-kioo-tchuan, or pleasing history, which has been rendered into English from a Portuguese version by Dr Percy, and which is considered as at once one of the most faithful translations of a Chinese work, and one of the best fitted to convey a correct idea of the sentiments and manners of that people.* In consequence of the early and frequent intercourse, which subsisted between the Chinese and Hindus, there is said to be an immense number of works to be found in the temples of Fo, translated from the Sanscrit language into the Chinese.

Chinese authors. But though China abounds in works of erudition, these are seldom produced by the labours and resources of private individuals. The youth of the country are so continually occupied with their studies and examinations in their progress to office, and so entirely engaged with the duties of their place, when they have obtained appointments, that they have no leisure for literary pursuits. The constant and regular removals also of the mandarins from one station to another, and the uncertainty of a son being able to preserve the rank of his father, prevent the accumulation of private libraries; and though there are generally large collections of books and manuscripts stored by order of government in the monasteries of the bonzes, by way of security, to which all the literati have free access; yet the greater part of these convents are at a distance from the cities, frequently situated in the midst of mountains, and thus not easily within the reach of literary men. **Imperial college.** All the great works, therefore, of Chinese production, have proceeded from the Han-lin, a kind of college, or body of select literati, who have their residence at court, and who act as secretaries to the emperor, or as superintendants of the imperial schools. The greater part of them, however, are lodged in a large and commodious building, where they are surrounded with all the literary treasures of the empire, and where they labour in concert, and without interruption, on such works as the emperor orders to be executed. As each of these has his proper employment, as all of them are interested in the general result, and as there is no restriction in point of expence or time; their united productions possess a degree of perfection, which is rarely found in the works of a private author. From this body proceed all the great historical collections, dictionaries, commentaries, &c.; and these works, printed at the expence of government in a most magnificent style, are distributed by the emperor as presents to the princes of the blood, prime ministers, principal tribunals, governors of provinces, and public libraries. **Ordinary publications.** In other respects, there are few publications and little printing in China, except a multitude of temporary and trifling productions, which are poured forth every month from the presses at Pekin, and which are speedily circulated throughout the empire. These consist chiefly of almanacks and calendars; manuals of medicine and devotion, of rites and ceremonies, and rules of good-breeding; predictions of good and bad fortune; moral maxims from ancient sages, and the exhortations of the existing emperor; novels, romances, or moral tales; comedies and laughable stories, popular songs and fables; receipts for cookery or physic, and similar productions, which are generally sold at a cheap rate, and of which the Chinese are said to be great readers. Daily papers also are printed in the capital, containing private anecdotes, domestic occurrences, notices of sales, and the virtues of quack medicines; **Freedom of the press.** and to a certain extent the press may be said to be free, that is, not under the necessity of waiting, before publishing, for any licence or imprimatur. But the summary mode of punishing any breach of morality or good order provides a sufficient security against any licentiousness in the press, as not only the printer and vender, but even the reader of any libellous or pernicious publication, would be equally obnoxious to the bamboo. As the superior mandarins also are the sole judges of the limits to be observed in such publications, it may be said that there is, strictly speaking, no real liberty of the press, or of any thing else in China; and it would be certain ruin to publish the slightest reflection upon the conduct of government, or of its principal officers.

General education. As learning is so essential a requisite in China for admission to office, the more wealthy classes endeavour to give to their children the best education; and they find a sufficient number of preceptors in those students who are candidates for the title of doctor. The government provides teachers for the children of the soldiery, but supports no other seminary throughout the whole empire, except the imperial college at Pekin; to which the mandarins of the four first orders, resident in the metropolis, those of the three first orders resident in the provinces, and those of the first and second orders in the military class, are entitled to send one of their children; where, after an attendance of three years, they are capable of being admitted to inferior appointments. There is not a city or village, however, in China, where a school is not to be found; the elements of education may frequently be obtained at the low rate of two dollars per annum; and it has been calculated, that about one half of the people are able to read and write.

Poetry. It is said, that the Chinese literati, employed only in useful studies, and in the pursuit of office, put very little value upon poetical compositions, except as a mere amusement in moments of relaxation; but that, nevertheless, a taste for the perusal of verses is general in the nation, and that there are few of their writers, who have not devoted a part of their leisure hours to the muses. At the same time, it may be affirmed, that, according to all our received ideas of poetical composition, there is, in strict propriety of speech, no such thing as poetry in the Chinese language; and it is only by analogy, that the name can be applied to a particular species of their literary productions. The nature of the language precludes every thing that constitutes the essence of a poem. The energy and beauty of expression among the Chinese depends not upon any measured arrangement of sounds, but upon a skilful choice of written characters; and it may be said, that Chinese verses (the merit of which can be appreciated only by the learned) are addressed rather to the eye than the ear.

They designate their poetry by the appellation or character *Shee*, which is compounded of *Yen*, a word, and *Shee*, a temple, that is, *the words of the temple*; an expression which is supposed to imply, that such a style of writing is derived from a divine origin, and designed for sacred uses. As the word *yen* signifies also to speak, it has been farther conjectured, that the Chinese name of poetry may allude to the mode of speaking or teaching in temples, and may thus imply an imitation of that figurative style, which the ancient orientals in general employed in their religious instructions.

---

* For a particular account of Chinese books, see *Histoire de l'Academie des Inscr. et Belles Lettres*, tom. 36, and Fourmont's *Grammat. Sinica*.

There are two kinds of Chinese poetry, which may be distinguished by the epithets written or painted, and oral or audible. The first is chiefly addressed to the eye, and its principal excellence consists in such a selection of characters as may convey the meaning in a concise expression, and, at the same time, excite agreeable associations in the mind of a Chinese reader. This latter effect is produced by bold metaphorical terms, by ingenious etymological combinations, or by allusions to the more important and interesting events in history. Many of these figures of speech, or rather figures of writing, are sufficiently fanciful, and far beyond the most profound conceits of our metaphysical bards. Others are so entirely applicable to Chinese history, as to be intelligible only to those, who are well acquainted with their ancient events and proverbs. Thus the head is denominated the *sanctuary of reason;* the ears, the *princes of hearing;* the eyes, the *stars of the forehead,* or *living pearls;* the nose, the *mountain of fountains;* the stomach, the *laboratory of aliments;* a mat for bedding, the *kingdom of sleep.* To *paint the tyger* is an expression which signifies *to drink hard;* because an ancient painter, when he was about to depict that ferocious animal, used to stimulate his imagination by copious draughts of strong liquor. A *peach tree and a spring of water* signify *the retirement of a sage;* because a Chinese philosopher, when fleeing from persecution, subsisted for some time in a desert place upon *peaches* and *water.* And the expression *she will not cut off her nose,* describes a gay widow in quest of a second match; because a beautiful widow is recorded in history to have mutilated her nose, that she might not be compelled to enter a second time into the married state.

In the second species, which is addressed to the ear, there are verses of a regulated measure, occasionally, though not uniformly, terminating in rhyme. In consequence of the small number of words in the spoken language, the poet is allowed to have one blank verse, at least, in every four of metre. This measured poetry is pronounced always in a recitative tone, which approaches to singing; and the particular notes, even, are frequently affixed to the written character. This tone is essential to the oral poetry; and, as there is frequently little rhyme in these compositions, the sole difference between verse and prose, often consists merely in the singing tone, with which the former is accompanied.

The most ancient and approved of the Chinese poetry is the *Shee-king,* mentioned among the sacred classics, which contains about 300 pieces, collected and revised by Confucius. They are chiefly of the oral species, and are generally repeated with musical cadences. As neither the expression of the visible character to please the eye, nor the accompanying tones addressed to the ear, can be represented to the European reader, it is not possible to give a fair specimen of such poetry; but curiosity may be gratified, to a certain extent, by the following extract from the *Shee-king,* which is a poetical record of a solar eclipse.

"Tché yué tché kiao
Tchou ge sin-mao
Gé-yeou ché tché
Ye koung tchè tcheou
Pei yue eul wei
Tsé ge eul wei
Kin tse shin min
Ye koung tcho ngai."

Literally translated.

"Tenth moon's conjunction, first day *sin-mao,* sun had eclipse: All portend bad. Whether sun covered or moon covered, people in general fear bad."

Among the first of modern Chinese poets is reckoned the late emperor Kien-long. One of his productions, entitled, "the praise of Mook-den," a city and district in Mantchoo Tartary, is of the written kind, and is a selection of characters, without measure or rhyme; but contains so much of the Mantchoo language, as to be unintelligible to a mere Chinese scholar. Another of his poems, "the Conquest of the *Miao-tse,*"* is of the second species, composed in a regular measure, accompanied by a kind of melody; and its 30 stanzas may be regarded as merely so many military bulletins, set to music, the first of which is as follows:

Nien se tchong tseoo ye tchoo shee
Moulan ing lee tee hong keo
Pen lai poo mo vouen koon pau
Shoo pouei kin siau vouen Kien-tchée.

Thus rendered verbatim.

Twenty-four middle time 8th month night 1st to 3d watch
Moulan camp banner letter brought red flag with 2 dragons
Principal made strange reward how could I believe army
Proclaim early morning nigh like see.

Thus Paraphrased by Mr Weston.

"It was on the 24th of the 8th moon, between the second and third watch, in the middle of the night, in the camp of Moulan, that they came to tell me of the arrival of a messenger from the army with a red flag. How could I believe, that, this night I should see the certain sign of victory, and have so early an occasion of proclaiming the glory and reward of my army."

Imperial receipt for infusing tea.

One of this emperor's most celebrated poems is an ode in praise of tea, or rather a receipt for the proper infusion of that beverage; which is thus translated by Mr Barrow.

"On a slow fire set a tripod, whose colour and texture shew its long use. Fill it with clear snow-water. Boil it as long as would be sufficient to turn fish white, and cray-fish red. Throw it upon the delicate leaves of choice tea, in a cup of yooe (a particular kind of porcelain). Let it remain as long as the vapour rises in a cloud, and leaves only a thin mist floating on the surface. At your ease, drink this precious liquor, which will chace away the five causes of sorrow. We can taste and feel, but not describe, the state of repose produced by a liquor thus prepared."

Ballads, &c.

The Chinese have their odes, elegies, eclogues, epigrams, satires, and even *bouts rimés;* and the common people are furnished with songs and ballads suited to their taste. These are frequently composed by their most distinguished writers, who have put into verse, for the use of the lower classes, their most celebrated moral maxims and rules of good breeding; and who vindicate the utility of these humble labours by the following proverb: "Though good grain should produce only straw, still it will benefit the soil by preventing the growth of weeds."

We add, from Mr Barrow, one of the most popular Chinese songs, entitled

---

* This poem has lately been translated into English by Mr Stephen Weston.

21 22 23 24 25 26 27
Tai you kung kan wha jin ma.

I.

1 2 3 4 5
How delightful this branch of fresh flowers!
6 7 8 9 10 11 12 13
One morning one day it was dropped in my house.
14 15 16 17 18 19
I, the owner, will wear it not out of doors;
20 21 22 23 24 25
But I will hold the fresh flower and be happy.

II.

1 2 3 4 5 6
How delightful this branch of the Moo-lee flower!
7 8 9 10 11 12 13 14
In the full pot of flowers blowing freely none excels it.
15 16 17 18 19 20
I, the owner, will wear this gathered branch;
21 22 23 24 25 26 27
Wear it, yet fear, the flower seen, men will envy.

Oratory.

The oratory of the Chinese is founded chiefly upon an imitation of their best ancient writers; and may be said to consist merely in an elevated style of writing, or to be the same as their poetry, without the musical notes. Its excellence consists in conciseness of expression, boldness of metaphor, a happy application of ancient maxims, and above all, in brevity of illustration. No superfluous ornament, or useless expression, or accumulation of inconclusive argument, is admitted in such compositions; and the best orations are those, which produce their effect, without exceeding the compass of a few lines. In what may be called the academical compositions of the literati, who are aspiring to degrees, there is a sufficient display of false eloquence, of unnatural images, unmeaning words, and excessive brilliancy; but such orators are denominated *golden mouths* and *wooden tongues* by their best judges, who approve only what approaches to the elegant precision and manly simplicity of their ancient authors. The Chinese rhetoricians pretend to distinguish oratory into an inconceivable number of varieties; but the designations of the several kinds are merely epithets, expressing the quality of the piece, or the disposition of its author. Thus they speak of *the eloquence of things*, which consists in the power of truth; *the eloquence of sentiment*, which is the effusion, as it were, of the orator's soul; *the eloquence of candour*, which banishes doubt or suspicion; *the eloquence of combination*, which is the fruit of much study; *the eloquence of wonder*, which subdues reason by astonishing the imagination; *the eloquence of singularity*, which contradicts received truths, and attracts by the appearance of original discoveries; *the eloquence of subtleties*, which is wrapt up in obscurities; *the eloquence of depth*, which produces reflection by its weighty instructions; *the eloquence of grandeur*, which approaches to the sublimity of the ancient classics, &c. Strictly speaking, indeed, there is no real oratory in China, as there is no oral address in the presence of judges or assemblies. It is only by memorials, petitions, and remonstrances presented to the emperor, or his tribunals, that a rhetorician can influence any proceeding; and, in no instance do the Chinese admit of those powerful modulations of voice, expressive gestures, and animated declamations, which contribute so much to the success of European orators. Affecting always to be grave and composed hearers, they wish their understanding to be calmly and gradually enlightened, and would be offended by any appearance of a wish to impress their feelings.

Drama.

The Chinese drama possesses none of the requisites of the European stage; observes none of the unities of time, place, or action; makes no distinction between tragedy and comedy; and exhibits the whole life of the hero, or even the duration of a whole dynasty, without any regard to regularity or probability in the plot. Every piece is generally divided into several parts or acts; every actor, when he comes forward, begins by informing the audience of his name, and the character which he is to support; and the same person generally performs several parts in the course of the piece. The dialogue, like the Italian opera, is delivered in a monotonous kind of recitative, with occasional risings and sinkings of the voice, to denote the emotions of the speaker; and the more violent passions of anger, joy, grief, despair are always expressed by singing. There is generally an accompaniment of music throughout the representation; and the pauses, particularly, are filled up by a confused crash of gongs, drums, trumpets, and cymbals. They have no scenery, but what is produced by the awkward use of human beings to represent inanimate objects; and Shakespeare's "man with lime and rough-cast to present a wall." is far outdone by a heap of Chinese actors, piled like logs above each other, to imitate a wall in the storming of a city or castle. To assist the imagination of the audience, also, in conceiving some change of scene, an actor rides round the stage upon a stick, humming a song, in imitation of a person making a journey; or he imitates the action of a person opening a door, and ascending a step or stair, in order to imitate his passing from one apartment to another. Females are not permitted to appear upon the stage; but eunuchs or boys are employed in their stead.

Their select pieces consist of a hundred historical plays published in one work, and supposed to have been chiefly produced in the fourteenth century. Only one of these, "the Orphan of China," translated by Father Premare, has appeared in a European version; and was the basis of Voltaire's tragedy of the same name. It is not considered, however, as a very faithful translation; and furnishes no proper specimen of the actual state of Chinese theatricals. The subjects of the more regular pieces are generally of a historical nature, referring to the more remote events, and represented in the ancient costume of China; and the catastrophe of the greater part, is generally the last paroxysm of a despairing lover, or the violent agitations of a criminal on the eve of execution. The Tartar Conquest is among the number of these representations; but there are no pieces founded upon events posterior to that æra. It has been affirmed by the French missionaries, that the ancient Chinese sages uniformly condemned theatrical representations; that they are rather tolerated than authorised by the existing laws of the country; that the modern literati rarely employ their talents in writing for the stage; and that even the editors of the Gazette would be subjected to censure and punishment, were they to debase its pages by any notices respecting their stage-players. Notwithstanding the excessive fondness of the Chinese for theatrical exhibitions, the office of comedian is so much despised by the people in general, that the managers of their theatres, or rather leaders of strolling companies, experience great difficulty in procuring a sufficient number of actors, and are frequently obliged to purchase, and to bring up children for the purpose.

Modern Chinese theatricals.

Their critics maintain, that the Chinese theatre has greatly degenerated since the Tartar conquest; and lament, like European censors, the depraved taste of modern times. It is said, that the principal personages of the empire have frequently private theatres in their houses, where they occasionally entertain their guests with more regular and established pieces; but the chief part of their public exhibitions, even in the presence of the court, consists of dancing, riding, wrestling, posture-making, and juggling tricks. The following description, by Lord Macartney, of the exhibitions on the emperor's birth-day, may be considered as a specimen of their higher style of performance. "The comedy began at eight o'clock, and lasted till noon." "The theatrical entertainments consisted of a great variety, both tragical and comical. Several distinct pieces were acted in succession, though without any apparent connection with one another. Some of them were historical, and others of pure fancy, partly in recitative, partly in song, and partly in plain speaking, without any accompaniment of instrumental music; but abounding in battles, murders, and most of the usual incidents of the drama. Last of all, was the grand pantomime, which, from the approbation it met with, is I presume considered as a first rate effort of invention and ingenuity. It seemed to me, as far as I could comprehend it, to represent the marriage of the ocean and the earth. The latter exhibited her various riches and productions, dragons, and elephants, and tygers, and eagles, and ostriches, oaks, and pines, and other trees of different kinds. The ocean was not behind hand, but poured forth on the stage the wealth of his dominions, under the figures of whales and dolphins, porpoises and leviathans, and other sea monsters, besides ships, and rocks, shells, sponges, and corals, all performed by concealed actors, who were quite perfect in their parts, and performed their characters to admiration. These two marine and land regiments, after separately parading in a circular procession for a considerable time, at last joined together and forming one body, came to the front of the stage, when, after a few evolutions, they opened to the right and left, to give room for the whale, who seemed to be the commanding officer, to waddle forward, and who, taking his station exactly opposite the emperor's box, spouted out of his mouth into the pit several tons of water, which quickly disappeared through the perforations of the floor. This ejaculation was received with the highest applause; and two or three of the great men at my elbow desired me to take particular notice of it, repeating, at the same time, "Hao kung haô, charming, delightful." "We had now wrestling and dancing, tumbling and posture-making, which appeared to us particularly awkward and clumsy, from the performers being mostly dressed according to the Chinese *costume*; one inseparable part of which is a pair of heavy quilted boots, with the soles of an inch thick. The wrestlers, however, seemed to be pretty expert, and afforded much diversion to such as were admirers of the *Palæstra*. A boy climbed up a pole or bamboo 30 or 40 feet high, played several gambols, and balanced himself on the top of it in various attitudes; but his performance fell far short of what I have often met with in India of the same kind. A fellow lay down on his back, and then raised his feet, legs, and thighs, from his middle perpendicularly, so as to form a right angle with his body. On the soles of his feet was placed a large round empty jar, about four feet long, and from two and a half to three feet diameter. This he balanced for some time, turning it round and round horizontally, till one of the spectators put a boy into it, who, after throwing himself into various postures at the mouth of it, came out and sat on the top. He then stood up, then fell flat upon his back, then shifted to his belly; and, after shewing a hundred tricks of that sort, jumped down upon the ground, and relieved his coadjutor." "A man came forwards, and after fastening three slender sticks to each of his boots, took six porcelain dishes of about 18 inches diameter, and balancing them separately at the end of a little ivory rod which he held in his hand, and twirling them about for some time, put them, one after the other, upon the points of the six boot-sticks above-mentioned, they continuing to turn round all the while. He then took two small sticks in his left hand, and put dishes upon them in the same manner as upon the other, and also one more upon the little finger of his right hand, so that he had nine dishes annexed to him at once, all twirling together; which in a few minutes he took off one by one, and placed them regularly on the ground without the slightest interruption or miscarriage." But in all these performances, and many others of the same kind, his Lordship declares, that he witnessed none at all comparable to the tumbling, rope dancing, wire-walking, and straw-balancing at Sadler's Wells; nor any feats of equitation in the style of Hughes and Astleys' amphitheatres. It is in fire-works alone, that the Chinese seem to excel all other nations in neatness, magnificence, and ingenuity of contrivance. "One piece of machinery," says Lord Macartney, "I greatly admired. A green chest, of five feet square, was hoisted up by a pulley to the height of 50 or 60 feet from the ground. The bottom was so constructed as then suddenly to fall out, and make way for 20 or 30 strings of lanterns, inclosed in the box, to descend from it, unfolding themselves from one another by degrees, so as at last to form a collection of at least 500, each having a light of a beautifully coloured flame burning brightly within it. This devolution and developement of lanterns (which appeared to me to be composed of gauze and paper) were several times repeated, and every time exhibited a difference of colour and figure. On each side was a correspondence of smaller boxes, which opened in like manner as the others, and let down an immense net-work of fire, with divisions and compartments of various forms and dimensions, round and square, hexagons, octagons, and lozenges, which shone like the brightest burnished copper, and flashed like prismatic lightning, with every impulse of the wind. The diversity of colours, indeed, with which the Chinese have the secret of clothing fire, seems one of the chief merits of their pyrotechny."

Similar exhibitions and theatrical entertainments were witnessed by the gentlemen of the Dutch embassy in 1795; in some of which, the officers of the court were themselves the performers. About the season of the new year the emperor made his appearance upon the ice in a sort of sledge, supported by figures of four dragons, and moved about by some of his chief mandarins, some dragging before, and others pushing behind. The four principal ministers of state were also drawn in like manner by inferior mandarins. Crowds of civil and military mandarins attended, some in sledges, some on skaits, and some amusing themselves at foot-ball upon the ice, the more expert of whom were rewarded by the emperor. The ball was then hung up in a kind of arch, and several mandarins passing it on skaits, shot at it as a mark with their bows and arrows. Owing to the form of their skaits, which were cut short under the heel, and the fore part turned up at right angles, the skaiters could not easily stop themselves on a sudden; and hence, when they came near to the side of the ice, or towards the quarter where the emperor was stationed, they tumbled in heaps one over the other. The other entertainments, exhibited, consisted chiefly of contortions of the human body, by posture makers and rope-dancers, with the addition of a kind of pantomime hunt, which was performed by men dressed in skins, and going on all-fours, to represent wild beasts, and by boys habited like mandarins as hunters; an exhibition, which was observed to afford great entertainment to the emperor and the ladies of the court, who were concealed behind Venetian blinds in an upper apartment. An entertainment was given after an eclipse of the moon, in which, besides a multitude of juggling tricks and puerile sports, there was likewise a pantomimical representation of the battle between the moon and the great dragon, who causes the eclipse. In this lunary contest, two or three hundred priests, bearing lanterns at the end of long poles, performed numerous evolutions, dancing and capering about the plain, or jumping over chairs and tables, to the infinite delight of the emperor and his courtiers.

Not only are the theatrical exhibitions of the Chinese thus mingled with such low absurdities and puerilities, as are little superior to the tricks and puppet-shows which amuse the populace at an English fair, but every species of obscenity and indecency also is brought upon their stage in so shameless a manner, that the most unpolished European seamen have often been known to leave the Canton theatres in disgust. The exhibitions, indeed, to which foreigners are admitted in this city, are asserted to afford no proper criterion for judging of the Chinese public places in general; but to be considered by the natives themselves as sufficiently good for the amusement of the despised barbarians of other countries. As it is not, however, pretended by those, who allege this palliation, that none but foreigners are allowed to be present at such representations, it clearly indicates a depraved taste, at least in the inhabitants of Canton, when such indecencies are exhibited in places of entertainment, which are open to the whole community.

ARTS AND SCIENCES. Science, strictly so called, can scarcely be said to exist in China; and not one of the arts has attained a high degree of cultivation. In the more useful arts of life, excepting agriculture, or rather horticulture, (for it is chiefly with the hoe and spade that the land is tilled,) they have made little progress; and in what are called the fine arts, or those which indicate taste, with the exception of the embellishment of garden ground, they are still in a state of barbarism. In those, which approach rather to the character of manufactures, pottery is the only one, in which they can be regarded as eminent, and that chiefly owing to the peculiar excellence of their materials; and in those, which discover great ingenuity, their pyrotechny alone surpasses that of all other nations.

Astronomy. Of all the sciences, astronomy is the most valued, but least understood by the Chinese, and they profess to trace back their acquaintance with its principles to the most remote periods. According to the Shoo-king, the revolutions of the heavens, and the length of the solar and lunar years, were known in the time of Yao, about 2357 years before Christ. Their astronomical observations, however, recorded during the long period which their annals embrace, are so exceedingly few in number, so obscurely detailed, and so doubtful in their whole circumstances, as to afford no evidence of the skill of the observers. But, however attentive and persevering their observance of the heavens, they have not on that account become more able astronomers; nor can it be said of them, as it has been of other nations, that their rage for astrology has contributed to their progress in astronomy. It does not appear that they were ever able to calculate eclipses; and their tables on this subject are mere registers of what has happened, and not predictions of what is to take place, founded upon astronomical computations. They are utterly ignorant even of the first principles of the science, and have nothing in their stead, but a confused jargon about judicial astrology. They still maintain all the vulgar notions, which their great philosopher inculcated more than 2000 years ago, namely, that the heaven above is round, and the earth a square fixed in the middle, with the element of water placed on the north side of it, that of fire on the south, that of wood on the east, and that of metal on the west; and that the stars are all stuck in the blue vault of the firmament, at the same distance from the earth. **Mathematical board.** From the earliest periods of their history, indeed, an astronomical board has formed one of their official departments in the government; but the principal, and almost the only business of this board, is to prepare a national calendar, in order to mark the returns of the seasons, to fix the dates of the public ceremonies, and to point out the most suitable times for important undertakings. A committee is annually appointed to superintend the astrological part of this calendar, which is chiefly composed of predictions respecting the weather, a list of all the lucky or unlucky days of the year, and a notice of the most proper times for taking medicine, for marrying a wife, for entering upon a journey, for laying the foundation of a house, &c. The astronomical part of their function, however, comprising tables of the sun's rising, of the new and full moon, of the motions of the principal planets, and of the moon's conjunctions with these luminaries, is generally committed to foreigners; and whenever the Chinese members have been left to their own resources in this branch of their duty, they have been involved in the grossest blunders. In the 13th century, when Gengis Khan first entered China, and his successor Kublai Khan conquered the country, their national almanack was found to be in the greatest disorder; and the conqueror, by inviting to his dominions learned Greeks from Bactriana, Mahommedan and Christian missionaries, succeeded in procuring their chronology to be adjusted, their astronomical observations to be rectified, mathematical instruments to be imported, and the whole empire to be properly surveyed and divided. The greater part of those learned men seem to have been expelled from the country, when the Tartars were driven from their sovereignty; and when China was again subdued by its present rulers, the Mantchoo dynasty, it was found that the calendar had become full of errors. Some German Jesuits, with Father Adam Schaal at their head, had been appointed to assist the tribunal of mathematics; but, when these were cast into prison in 1664, the whole astronomical system was again thrown into such confusion, that Father Verbriest, upon being appointed by the government, in 1669, to correct the calendar, found it necessary to cut off a whole month. Of late years, this office of regulating the national almanack has been committed to the Portuguese missionaries; and three of them were entrusted with this important charge, at the time of Lord Macartney's embassy.

Distribution of the planets.

The Chinese reckon seven planets, including the sun and moon. The sun is represented by the figure of a bird within a circle, and presides over the year and the seasons. The moon is figured by a rabbit pounding something in a mortar, and presides over the division of time. The other five are, *Too*, the earth, which corresponds with Saturn, and reigns to the end of summer; *Mo*, wood, which corresponds with Jupiter, and presides over the spring; *Ho*, fire, which corresponds with Mars, and presides over the summer, mournings, and public works; *Kin*, metal, which corresponds with Venus, and presides over the autumn; and *Shooy*, water, which corresponds with Mercury, and presides over the winter. They have arranged the stars under different constellations, the names of which bear a reference to the different parts of the government and empire of China; and the firmament is divided into four quarters, each of which contains seven of these constellations. These twenty-eight constellations compose the zodiac, which they call *the yellow way;* and the equator, which is named the *flesh-coloured way*, is divided into twelve palaces, or portions, of thirty degrees, each of which is again divided into two, thus forming the twenty-four Tsie-kee, which refer to the different seasons and periods of the year.*

Division of the year.

They divide the year into twelve moons, or lunations, and make an intercalation of one month in the 3d, 6th, 9th, 11th, 14th, 17th, and 19th year, in a period of nineteen years. They begin the year with the first new moon which appears after the first degree of Aquarius; and the whole consists of 354 days. The months consist some of 30, and some of 29 days; and are divided, sometimes into four, and sometimes into three parts. The day is divided into twelve hours, each, of course, containing two of ours; and the first begins at 11 o'clock in the evening. Each hour is divided into two half-hours, and each half into four quarters. The hours have their appropriate appellations, and bear also the names of different animals, viz. the rat, the ox, the tiger, the hare, the dragon, the serpent, the horse, the sheep, the ape, the hen, the dog, the hog. The night is farther divided into five watches, which vary in length, according to the duration of the darkness, and the first of which begins about 8 o'clock of the evening.

Astrological notions.

The planets are considered by the Chinese as influencing the events of human life, and much is made to depend upon their appearance and positions. When the colour of the sun is pale, it is a token of approaching calamities, or of the death of a prince; and its eclipse is understood to be necessarily followed by rebellions. Hence it has been justly remarked, that, as the persons appointed to observe the heavens, will naturally wish to find as few ominous aspects as possible, and, consequently, must make their observations under the strong influence of superstitious prejudices, astronomical science must always be in a very low state in China. The occurrence of an eclipse is there viewed as an event affecting the stability of the empire, or the safety of the prince; and the whole nation are assembled to the spectacle by express orders of the government. The officers of state give public notice of the time when such a phenomenon is expected, according to the calculations of the national almanack. The public functionaries put on mourning; and all business is suspended. The members of the mathematical board, and other learned men, assemble at the palace to observe the agreement of the eclipse with the prediction; and, as soon as the observation commences, they fall down upon their knees, bowing their heads repeatedly to the ground; while the gongs, trumpets, kettle drums, and all kinds of noisy instruments strike up at once, to frighten the dragon which is supposed to have beset the suffering luminary. It is related, that, on one occasion of this nature, the intervention of clouds having prevented the eclipse from being seen, the Chinese grandees hastened to congratulate the emperor, upon the regard which heaven had testified for his virtues, in sparing him, at this time, the affliction of beholding the sun under an eclipse.

Eclipses.

Geography.

Their knowledge of geography is equally defective; and they consider the earth as a plain square surface, of which their country occupies the central part. Even their plans and charts of their own empire were utterly rude and incorrect sketches, without either rule or proportion, till they were provided by the indefatigable labours of the Jesuits with their present accurate maps and surveys.

Arithmetic.

They are totally ignorant of algebra and geometry; and their arithmetic is altogether a mechanical system. By the most learned, as well as the most illiterate of the people, all their calculations are performed by means of a machine, apparently of Chinese origin, called in the common dialect Swan-pan, and, in the mandarin pronunciation, Soen-poen. It bears some resemblance to the Abacus of the Romans, and consists of ten rows of balls, strung upon copper wires, and divided in such a manner, that the upper part of each row contains two balls, each of which is reckoned five; while the inferior portion has five balls, each of which represents an unit. By the aid of this instrument they produce a kind of decimal arithmetic in a very easy and expeditious manner; of which a figure and description may be seen in Barrow's *Travels to China*, p. 296. The Chinese do not express numbers by figures; but write the sums at length in words; except in what may be called their current hand, which frequently abridges the characters; and, in which, for instance, instead of the two words or characters, San-she, 30, they would draw three perpendicular lines crossed by another in a horizontal direction.

Natural philosophy.

They have a practical knowledge of some of the most obvious effects produced by natural causes; but no branch of physical science is pursued as a subject of investigation. They have very little acquaintance with pneumatics, hydrostatics, electricity, or magnetism; and, except making concave and convex lenses of rock crystal, for spectacles or burning glasses, they are equally ignorant of optics. The single microscope, indeed, was found in use among them; but they are unacquainted with the art of assisting vision by a combination of lenses.† A convex lens is very commonly carried by individuals to light their tobacco pipes; but they have not sufficient knowledge of its properties to enable them to appreciate the scientific improvements of these articles by Europeans; and they expressed no admiration of the immense and powerful burning glass, which constituted one of the presents to their emperor from the British embassy. See BURNING INSTRUMENTS, p. 142.

---

* Of all these particulars, see a minute account in De Guignes' *Voyage a Pekin*, tom. ii. 423, &c.

† Even in making spectacles, they grind the glasses at random; and when the purchaser chooses such as he conceives most fitted to his vision, he cannot be certain that both the glasses have the same focus.

Chemistry.

They are totally ignorant of chemistry, as a science; but are acquainted with many of its practical applications. The process of smelting iron is well known among them; and they produce a very thin and neat kind of cast iron ware, which they render less brittle by annealing in heated ovens. They are able also to convert the same metal into an inferior kind of steel, but their manufactures of wrought or malleable iron are extremely deficient, both in quality and workmanship. In the other metals, their skill is very considerable, and they produce a great variety of the neatest trinkets and jewellery. They display great ingenuity in cutting different kinds of stone into groups of figures and landscapes, in cutting and polishing the harder kinds of which, they make use of the powder of rock crystal. They have a knowledge of the effect of steam as a more powerful instrument of heat than water, and employ a kind of Papin's digester for softening horn; but they have no acquaintance with its elastic nature, and make no application of it to machinery. Though utterly devoid of all theoretical notions of colour, they know how to extract from vegetable, mineral, and animal substances, a variety of the most brilliant colouring materials, which they have the art of mixing up in every possible shade and tint, and which they can communicate to cloth, paper, and porcelain, in the richest and most lively hues. They are well versed, also, in the practice of distillation; and prepare from various kinds of grain, especially from rice, an ardent empyreumatic spirit, which they call *San-tchoo*, and which is said to have some resemblace to the whisky of Scotland. Other instances of their practical application of chemical principles will occur under the head of Manufactures.

Medicine.

The Chinese are said to have directed their attention to the cultivation of the healing arts, from the most remote periods; and to possess a mulutude of writings on that subject. But, however these assertions may be received, it is certain, that they have made very little progress in this most important science; that there are no schools of medical instruction in the empire; and that the profession is held in no degree of estimation. Every person is free to exercise the trade of a physician; and those, who wish to be duly prepared for practice, place themselves under the tuition of one of the faculty, who communicates his secrets and his skill. The eunuchs about the palace are generally accounted the most eminent practitioners, and the priests, for the most part, exercise the profession; but the great proportion of acting physicians are to be found among the lower classes of the community, and the multitude of quacks and nostrum venders is said to be immense. The Chinese physicians are altogether ignorant of physiology or the theory of the human frame, as well as of pathology, or the causes and symptoms of disease. They are utter strangers also to every branch of anatomy, as it would both be contrary to all their customs, and wholly impracticable for the weak nerves of a Chinese to open a dead body. It has been ascertained, in opposition to the assertion of the missionaries, that they are entirely unacquainted with the circulation of the blood; and their whole art is limited to the study of the pulse.

Theory of medicine.

According to their theory of medicine, vital heat and radical moisture are the two natural principles of life; the former of which they suppose to have its seat in the heart, lungs, liver, and kidneys; while they place the latter in the intestines, the number of which they reckon to be six. Of this heat and moisture, the blood and spirits are the vehicles, conveying them from their respective seats to the other parts of the body. Every disease, they imagine, acts successively upon the heart, the liver, the lungs, the stomach, the entrails, and the kidneys; and its passage from one of these parts to another, produces a crisis, of which it is of the utmost consequence to know how and when to take the advantage.

Diagnostics.

They pretend to judge of the state of a patient, and to determine the nature of his disease by the sound of his voice, the colour of his face and eyes, and the appearance of his tongue, nostrils, and ears; but it is upon the state of the pulse, that they found their most infallible prognostics. They suppose, that every particular part of the body has a separate pulse of its own, and that each of these again has a sympathetic pulse in the arm. The skill of the physician consists in discovering the seat and nature of the disease, by ascertaining the prevailing pulse in the body, in consequence of feeling the corresponding pulsations at the wrist. The pulse of the patient, therefore, is always examined with the greatest formality and deliberation; and the physician proceeds, without asking any questions, to inform the patient where he feels pain, what parts of his frame are affected, and in what manner the disorder will terminate. But, before pronouncing his opinion, he takes care to become secretly acquainted with the case of the patient; as his reputation always rests more upon assigning the true cause of the disease, than upon his success in removing it. That their information is not derived merely from the indications of the pulse, is manifest from the modes in which the female pulse is felt. As it would be contrary to all sense of propriety in China, for a stranger to touch the hands of a woman, a silken cord is fastened to the wrist of the sick lady, and passed through an opening in the wall to another apartment, where the doctor, by applying his hand to the string, pretends to distinguish the beats of the pulse. Like all oracular personages, however, unless they have been able, by other means, to learn the feelings of the patient, they generally ascribe the disorder to a cause of universal application, viz. to Fong-shooy, that is a good or bad fortune, and to heat or cold.

Mode of feeling the pulse.

Medical writings and practice.

The best of their medical treatises are mere herbals specifying the names, and qualities of plants; and their prescriptions consist chiefly of cordials extracted from fruits and herbs, and of strict regulations in point of diet. Their principal remedies from the vegetable kingdom are ginseng, prepared in seventy-seven different ways, rhubarb, China-root, and tea; from the animal kingdom petrified crabs as an antidote against all kinds of poison, musk, snakes, beetles, centipedes, the aurelia of the silk-worm, and other insects, the flesh, gall, skin, bones, and ivory of the elephant, the flesh, fat, milk, hair, and even the dung of the camel; from the mineral kingdom, saltpetre, sulphur, native cinnabar, &c. Opium is more frequently administered as a cordial to raise the spirits, than as a remedy against disease.

Surgery.

Their surgery, it may easily be conceived, is equally defective; and consists chiefly in setting a simple fracture, reducing a dislocation, drawing blood by scarifying or cupping, and sometimes burning the skin with hot pointed irons, or puncturing it with silver needles, and then setting fire to the leaves of certain plants, especially of mugwort, laid upon the place. Various other chirurgical operations, cleansing the ears, cutting corns, pulling the joints to make them crack, twitching the nose, and beating on the back, are performed by the barbers.

They are so afraid of cutting instruments, that even blood-letting with the lancet is never practised; and still less is amputation in any case attempted. Even the most simple operation is seldom undertaken, not only owing to the ignorance of practitioners, and the timidity of the patient, but in consequence, also, of the dread of an existing law, by which it is enacted, that if a wounded person be taken under any one's care with a view to effect his recovery, and if he should happen to die under his hands, then, unless the physician or friend can produce undeniable evidence how the wound was inflicted, and that the sufferer survived it 40 days, the person in whose hands he was found at his death, is made responsible for his life. So low, in short, is the state of the healing art in China, that the emperor of that extensive, populous, and wealthy country, according to the opinion of an eminent physician (Dr Gregory), could not command in his whole dominions, such medical aid as a smart boy of 16, who had been apprentice for one year to a well-employed Edinburgh surgeon, would be able to afford.

Architecture.

The Chinese architecture, bears no resemblance to that of Europe; and is not easily described by the usual terms of art. Their houses in general have nothing remarkable in their external appearance, and even their public edifices are distinguished rather by their extent, than their magnificence. Their whole style of building is represented by intelligent observers as extremely slight and ill-proportioned, inelegant in the design, and clumsy in the execution. All their dwellings are supposed to have been originally constructed after the model of a tent, with a carved roof, and wooden pillars round the brick wall, in imitation of the poles which support the sides of the tent. The external form and aspect of all the houses are extremely similar; and the habitation of a grandee in the capital is distinguished from that of a tradesman, chiefly by being surrounded with a high wall, and by occupying a greater space of ground. The dwellings of the peasantry, indeed, are in general extremely wretched, and little better than huts, consisting of low brick or earthen walls, covered by a slender roof of straw or of reeds. The habitations of the ordinary inhabitants in cities are confined within narrow limits; and a small court with two or three low-roofed apartments, forms the lodging of a whole family. The walls are generally of wood, occasionally of brick, but rarely of stone; and are neither solidly constructed, nor properly founded. The roof is commonly composed of tiles, formed in the shape of a canal, and those which are placed at the lower extremity, are, for the most part, curiously wrought and differently shaped. The lower stories are raised a little above the surface of the ground to avoid the moisture, and are paved with bricks or square tiles. The second flats are chiefly employed as store-rooms, and the stairs, in constructing which the Chinese architects are extremely unskilful, are little better than upright ladders.

Ordinary houses.

The houses of the more wealthy are distinguished by their large courts, galleries of communication, and variety of gates. The ground plot of 300 or 400 feet is laid out into ten or twelve courts paved with tiles. In some of these courts are three or four tent-shaped houses, standing upon stone terraces, which are about three feet above the level of the pavement; and from each of these apartments and courts are galleries of communication, consisting of colonnades of red wooden pillars resting on stone, leading to the adjoining parts of the habitation, so that every part of it may be visited without being exposed to the sun or air. The floors of the apartments are paved with bricks or clay; the ceiling is formed of bamboo laths covered with plaister, or is left altogether open without any thing to conceal the rafters. The windows are without glass, but are furnished with oiled paper, horn, silk gauze, or pearl shell, as a substitute. The walls are generally whitened with lime made from shells, or covered with white paper; and some of the rooms have holes in the corners, by way of fire places, from which the heat is conveyed through flues in the walls, or under the floor. The apartments of the ladies have frequently two stories, the uppermost of which have often no light, and are seldom so good as the common garrets in England. The furniture consists of a table, a few clumsy chairs of varnished wood, which on days of ceremony are covered with red cloth, some porcelain dishes filled with lemon trees or other shrubs, copper vessels for burning perfumes, and lanterns of various forms, made of paper, silk, ivory, or horn, and sometimes ornamented in a very expensive manner. Looking glasses are very rarely found in Chinese apartments, and little attention appears to be paid to internal decorations. Among the higher ranks, the beds are large and splendid, the posts gilded and adorned with sculpture, the curtains of fine gauze in summer, and silk in winter; but, in most cases, especially in the northern provinces, the beds are merely benches in the wall, constructed of brick, and heated by a stove on one side, the fire of which is frequently lighted from without. These beds, which are larger or smaller, according to the number of the family, are frequently covered with mattrasses during the night, which are replaced by a mat or carpet through the day, and the bed then becomes a kind of couch, upon which the family sit at work.* In the courts, are generally placed pots of flowers and shrubs, or jars filled with water, containing a variety of small fishes; and these courts are sometimes roughened with rocks and excavations in imitation of nature, and upon their ledges or projecting points, pots of shrubs and stunted trees are carefully distributed. A water closet, or suitable place of retirement, is not to be found in any Chinese dwelling or city; but large earthen jars, with narrow tops, are used for the purpose, and sometimes merely a stick, placed across a hole in a corner, is made to answer the end. The principal attention is paid to the position and construction of the gates, which in a great house are generally three in number, of which the middle one is the most magnificent, and is only opened for the admission of strangers of rank, or for the use of the master of the house on occasions of ceremony.

Apartments of the palace.

The lodgings, assigned to some of the gentlemen in the train of the British embassy, consisted of three or four rooms in a small court, surrounded with a wall, as high as the roofs of the buildings. Each apartment was about twelve feet square, the walls completely naked, the ceiling broken in, the lattices of the windows covered in some places with paper, and the doors made of old bamboo screens. In one of them, was an old table with only two or three chairs; and, in the rest, nothing but a little raised platform of brick-work, upon which were laid mattrasses to form a bed. Yet these rooms were within 200 yards of the great hall of audience in the imperial palace at Pekin; and had been the apartments of a great man, or officer of state. The greater part of the other buildings, within the precincts of the palace, were equally miserable hovels; and even the dwelling of the emperor himself, when divested of the painting and gilding, is pronounced by Mr Barrow to be inferior in solidity and furnishing to the barns of a substantial English farmer. The principal hall of audience in this palace was about 110 feet in length, 42 in breadth, and 20 in height. It stood upon a platform of granite, raised about four feet above the level of the court. A row of large wooden pillars surrounded the building, and supported the projecting roof. A second and corresponding inner row, with brick work between the columns to the height of four feet, formed the walls of the apartment. The spaces, above the brick work, were filled with a kind of lattice-work, covered with large sheets of oiled paper, and were capable of being thrown open on public occasions. The wooden columns had no capitals, and no other architrave, than the horizontal beam, which supported the rafters of the roof. Close to this beam, and between the upper parts of the columns, was a broad screen of wood painted with the most vivid colours and interlarded with gilding, the whole being covered with a net-work of wire to keep off the birds. The floor was paved with grey marble flags laid chequer-ways; and the ceiling was painted in circles, squares, and polygons variously coloured, and whimsically arranged. The throne, made entirely of wood and admirably carved, was placed in a recess, and supported by pillars of a red colour. On each side of it, stood a circular fan, made of the wings of a pheasant and mounted upon long polished poles of ebony. A pair of brass kettle drums, and of ancient procelain vases, two large paintings, a few volumes of manuscripts, and a table at one end, supporting an old English chiming clock, composed the whole furniture of this state apartment. The other edifices in the palace surpassed the ordinary buildings chiefly in their magnitude. Their walls were higher, their roofs of greater expanse, their wooden pillars of larger diameter, their painting and gilding more abundant, but none of them exceeded one story in height, and they were all equally unprovided with grates, stoves, curtains, looking glasses, sofas, bureaux, chandeliers, book cases, prints and paintings, and the other numerous elegancies and conveniences of furniture in European habitations.

---

* The bedding consists generally of matting made of reeds or bamboo; a cylindrical wooden pillow, covered with leather; a kind of rug or felt blanket, made of the hairy wool of the broad-tailed sheep, not spun and woven, but beaten together as in the making of hats; and sometimes a mattrass stuffed with wool, hair, or straw.

Temples and pagodas. The temples are constructed upon the same plan as the houses, with the addition of a second, and sometimes of a third story, one above the other; and their wooden pillars are generally of larch fir, without any fixed proportions, invariably painted red, and sometimes covered with a coat of varnish. The pagodas, which are frequently composed of five, seven, or nine rounds or roofs, but always an uneven number, and which are from 80 to 160 feet in height, are the most striking objects in China; but are commonly so ill constructed, and with such bad materials, that they soon fall into ruins. They are larger or smaller, according to the importance of the cities, in the neighbourhood of which they are erected. It has been conjectured, from this circumstance, that they were originally built as signal stations. They sometimes appeared as appendages to the temples, though never used themselves as places of worship; and they seemed frequently to have been constructed in different parts of the country merely as embellishments to the grounds. The gentlemen of the British embassy observed none, in the whole of their progress, that could be considered as a late erection; but the greater part were in a ruinous state; and the specimen of a pagoda in the gardens at Kew is said to be equal to the very best of those which were noticed by them in China.

ity gates. The gates of the cities are, next to the pagodas, the most conspicuous structures, and are generally square buildings, rising several stories above the arched gateway, covered like the temples with one or more large projecting roofs, and frequently furnished with port holes in their sides, as described under the head of Fortifications.

Triumphal arches. The triumphal arches are the most numerous buildings, and are sometimes constructed of wood instead of stone. They are almost all of the same form, consisting of three arches or gateways, of which the middle one is the most elevated, ornamented with sculptured flowers and other figures, seldom exceeding 25 feet in height; and generally deficient in this respect, that their size is too massy in proportion to their elevation.

Sepulchres and tombs. In the cemeteries, or burying grounds, which are generally very extensive, there is a greater variety of architecture to be seen, than in the habitations which compose their cities. Sometimes the dead are deposited in houses resembling in every respect those of the living, except that they are of a diminutive size; and sometimes in an ornamented vault of a square, or hexagon, or octagon figure. Over the graves are erected also round, or square, or angular columns. But the most common structure in the case of persons of rank, consists of three terraces, one above the other, inclosed by circular walls. These terraces are ornamented with the figures of slaves, horses, cattle, and the other favourite objects of the deceased; while the entrance of the vault, which is in the centre of the uppermost terrace, is covered with the inscription or epitaph.

Bridges. There is great variety and beauty in the Chinese bridges, which are generally light and elegant to the view, but seldom constructed with much solidity or strength. Though they have a fine appearance when newly built, they soon begin to fail; and many of them were observed, by late travellers in that country, to be in such a state of dilapidation, as to be scarcely passable with safety. Many of them are altogether destitute of parapets or side-rails; and the Chinese government pays much less attention either to their original construction, or future repair, than has been supposed. The form of the Chinese bridges is very various. Sometimes they are quite level to the line of the road, and sometimes have the central arches considerably elevated, so that, in some of the smaller, bridges, there is an ascent at each end by easy steps. The arches are sometimes pointed like the Gothic, sometimes semicircular, sometimes of the horseshoe form; and their piers are occasionally of such extraordinary height, that the largest of their vessels, about 200 tons burden, can sail below the span of the arch without lowering their masts. The arches are, in some instances, formed of small stones pointing to a centre, as in Europe; and some of the vaults and arches in the great wall, built in this manner, are said to be well turned. But, in general, each stone is from five to ten feet in length, and is cut in such a manner as to form a segment of the arch; while, instead of a key-stone, ribs of wood, fitted to the convexity of the arch, are bolted through the stones, with iron bars fixed into the solid part of the bridge; or the curved stones are mortised into long transverse blocks of stone, which run along the whole depth of the arch. In many instances, the pillars only are of stone, and beams of wood are laid across to form a floor. One of the most remarkable of the more ancient Chinese bridges, seen and described by M. De Guignes on the road to Pekin, was at Tsotcheoo. It was divided into two parts by a small island, and its whole length was about 600 feet. The parapet was composed of slabs of marble about six feet long, fixed by means of grooves upon a number of small pillars about four feet high, and was decorated in different places with figures of elephants in marble, which appeared to be well executed. Another is mentioned by Mr Barrow, which consisted of 90 arches, thrown across the arm of a lake which joins the great canal, the central arches of which were about 30 feet high and 40 wide, and the whole length of which was nearly half a mile.*

The great wall.

The most stupendous work of masonry in China is the great wall, which separates the empire of China from northern Tartary. The date of this remarkable fortification is not easily ascertained, as certain parts of it appear to have been constructed at different times by the princes of Tchao and Yen, about 250 years before Christ; but it was in the reign of the Emperor Shi-hoang-tee, about 214 years before the Christian era, that these separate portions were united, and the wall completed in its whole extent. It is said, that every third man throughout the empire was summoned to assist in the building; that in those places, which were too steep to admit of horses or carriages being used, the workmen stood so close for many miles, as to be able to hand the materials from one to another; that, so diligently was the work carried on, that the whole was finished in the space of five years; but that, owing to the fatiguing journies, and change of climate, which the labourers from the distant provinces had to undergo, the greater part of those, who were employed in the work died before its completion. It begins at its eastern extremity with a strong bulwark, or large pile of stone, raised in the yellow sea, and proceeds westward through the provinces of Pe-tche-lee, Shansee, and Shensee, till it terminates near the city of Kin, on the yellow river, in the impassable mountains and sandy deserts, which begin from that point to cover the western frontiers. It is carried across rivers, vallies, marshes, and over the top of the highest mountains, without a single interruption in its course, except by a ridge of inaccessible mountains near the city of Suen, in the province of Pe-tche-lee, to which it is closely united on each side, and by the river Hoang-ho, which passes through it in its progress to the sea; while rivers of a smaller size find a passage by means of arches like those of a bridge, without breaking the line of building. Various calculations have been made respecting its extent; but it seems to be generally agreed, that, including its numerous windings, it cannot be estimated at less than 1500 miles in length. The foundation consists of large square stones laid in mortar; but the rest of it resembles much the wall of Pekin, and is composed of an earthen mound, cased on each side with brick or stone. The top is paved with flat stones, and is so broad in many places, that six horsemen may easily ride abreast upon it. Where it passes over steep rocks and elevated grounds, it is perhaps not above 15 or 20 feet in height; but in the vallies and plains, it is not less than 30 feet high; and in those places is rendered doubly defensible by means of large projecting square towers, at the distance of a bow-shot from each other. It has been remarked, however, that, towards its western extremity, it is merely a mound of earth, and very defective in various places; low and defenceless even in very assailable situations; while in other parts it is continued, at an unnecessary expence, along mountainous ridges, which present of themselves sufficiently insurmountable obstacles to an invading army. It is, nevertheless, justly accounted the most enormous fabric in the known world; and it has been computed, that, including the earthen part of the mound, it would furnish materials sufficient to surround the earth, on two of its great circles, with two walls, each of them six feet high and two feet thick. It has been farther calculated, that all the dwelling-houses of Great Britain, supposing them to amount to the number of 1,800,000, and to average 2000 cubic feet of masonry, would not be equivalent to the solid contents of this immense building.

Grand Canal.

Nearly equal to this extensive work in grandeur, and superior in point of utility, is the imperial, or grand canal. The Chinese refer its origin to a much earlier date than that of the great wall; but it does not appear to have existed in its present improved state, and immense extent, above 400 years. When Shee-tsoo, the first emperor of the dynasty of the Mogul Tartars, fixed his residence at Pekin in 1267, and found that the conveyance of supplies to that city, by sea, was attended with innumerable risks and inconveniences; he began the formation of the Yun-ho, or grand canal in 1289, which was afterwards enlarged in 1369 by Tay-tsoo, an emperor of the Chinese dynasty of Ming, and at length united with the river Hoang-ho, and brought to its present state in 1409, by Yong-lo, one of his successors. It traverses the province of Shang-tong, and a part of Kiang-nan, and enters the river Hoang-ho at the city of Yang-kia-yn. It resumes its course at Tsin-kian-poo, passes by Yang-tcheoo-foo, and discharges itself into the Yan-tse-kiang at Koos-tcheoo. It begins, once more, on the other side of the river at Tsin-kiang foo, and continues its progress to the city of Hang-tcheoo-foo, where it completes a tract of more than 300 leagues. It is thus carried from north to south, in such a manner, as to cut at right angles the three great rivers Eu-ho, Hoang-ho, and Yan-tse-kiang, which carry off its superfluous water to the sea, while it receives a sufficient supply from the smaller streams in its course. It is bordered by strong dikes, sometimes cased with stone, but commonly constructed of alternate layers of earth and straw. To accommodate the general level of the canal to the several levels of the feeding streams, it has been necessary, in many places, to cut a channel to the depth of 60 or 70 feet below the surface; and, in other places again, to construct embankments along swamps and lakes to the extent of several miles, and often 20 feet above the level of the surrounding country; so that a sheet of water 200 feet wide, is seen rolling along at the rate of three miles in an hour, on a level often with the tops of the walls of the cities on its banks. The general slope of the country, in the course of the canal, is from north to south; and the middle point is found to lie between the rivers Eu-ho and Hoang-ho. It is chiefly therefore towards the north, that the level is preserved by cutting the channel to a considerable depth; and towards the south, that it is forced above the surface of the country by embankments of earth and stone. In the more hilly and uneven tracts, no locks are employed; but the canal is interrupted by an inclined plane; and the vessels, by means of large capstans, are hoisted up the one side out of the water, and lowered into it on the other. Where the canal is on a level with the surface of the fields through which it flows, small ditches are dug in its banks to let some of the water pass off into the adjacent soil, and bridges are thrown over these openings to preserve the communication. As an additional mean of preserving the level of the water, there are flood gates placed at certain distances, composed of large planks sliding in grooves, which are cut in the sides of stone abutments.

---

* See, under the article BRIDGE in this work, an account of some other remarkable Chinese bridges, and the observations of one of our most eminent engineers on the subject of these structures.

Antique ruins. There are no ancient architectural ruins in the Chinese empire; and, except the Great Wall, the Grand Canal, the walls and gates of some of the cities, and a few of the oldest pagodas, it is supposed, that there is not a single building in the whole country, which has existed above three centuries.

Sculpture. The Chinese artists are able to carve very skilfully in wood, ivory, or stone; but they execute the figures of men and animals in the most miserable style imaginable. They have no idea of order, attitude, or proportion; and there can nothing be conceived more monstrous and grotesque, than the figures, which adorn their bridges, temples, and tombs. These even are seldom cut in stone, but are most frequently made of baked clay, covered with varnish, paint, or gold-leaf. The triumphal arches, so highly extolled by the missionaries, are nothing but four-sided blocks of wood or stone, covered with inscriptions, but altogether devoid of any real ornament or grandeur; and it has been affirmed by recent travellers, that there is not a statue, or a column in the whole empire, which deserves to be noticed.

Painting. In painting, the Chinese resemble the Hindoos, Mexicans, and Peruvians, and display extraordinary powers of the most minute imitation, without the smallest portion of scientific knowledge, or of original invention. They will draw the exact number of petals, stamina, thorns, spots, &c. of a flower, and will even count, with the utmost exactness, the scales of a fish; but they faithfully represent every defect, as well as excellence, in the object of their imitation; and have been known to be so very deficient in judgment and information, as to unite, in one figure, the flower, the stalk, and the leaves of different plants. They depict, indeed, with unrivalled exactness and brilliancy, the colour of flowers, birds, and insects; but they are utterly unable to mix and soften their tints, to apply properly the lights and shades, or to convey the smallest idea of distance and perspective. **Perspective.** They even consider the diminished appearance and faded colouring of distant objects, as the consequence of a natural defect in the organ of sight, and look upon it as a most absurd practice to represent such an imperfection upon canvass. They always take a bird's eye view of their landscapes, and place themselves successively in the front of every part, whatever be its position or extent. There is thus no particular point in their paintings, from which the view is taken; and in order to express the distant figures, they represent the appearance of clouds dividing them as it were in two. Their emperor, particularly, must never be represented like another man; and though he should be drawn in the most distant part of a painting, it is necessary that his head be much larger than those of his attendants. They dislike shades, and consider them as defects in European paintings; an instance of which was given by one of their ministers of state, who remarked, upon viewing a portrait of his Britannic majesty, that it was a pity it should have been spoiled by the dirt on the face, meaning the shade of the nose. They catch pretty exactly the features of the human countenance, but execute the colouring very ill. They are still more deficient in the art of proportioning a human figure; and M. De Guignes describes a full length portrait, of an European by a Canton limner, as resembling nothing so much as a sugar-loaf reversed. The specimens of Chinese painting, which are brought to Europe, are pronounced to be the best of their productions, as they are generally executed by Canton artists, who are said to have acquired a superior taste to the rest of their countrymen, by being employed to copy the various European prints and drawings, which are carried thither for the purpose of being fixed upon porcelain vessels. They are all possessed, however, with a sufficient conceit of their pre-eminence in this, as in other arts, over all other nations; and have rejected, with disdain, the plans and proposals of some European artists, to establish schools of painting in their country.

Music. Music would appear, from the Chinese records, to have been always highly esteemed among them; and, in ancient times, to have been employed as an instrument of government, and the handmaid of good morals. No public ceremony was then performed without the aid of music; and the office of prime musician was one of the most important in the state. He was at once physician, moralist, poet, and historian; physician, because he suited his tones to the temperature of the air and the seasons of the year; moralist, because he taught lessons of virtue; poet, because he composed verses, which he accompanied with his music; and historian, because, being employed to celebrate the acts of eminent men, it was necessary, that he should be able to draw from the page of history the most memorable transactions, and such as were most deserving of being transmitted to posterity. The Chinese, like the Greeks and Egyptians, speak of their ancient music, as an instrument of extraordinary power, often producing the most wonderful effects; and as these other nations had their Hermes and their Orpheus, so the country of China boasts of a Lyng-lun, a Pin-moo-kia, and especially a Kuei, who were able, by their skilful sounds, to soften the hearts of men, and to tame the most ferocious animals. The Emperor Shun, according to the Shoo-king, among other important duties of his high station, witnessed the performance of the instituted dances, and caused the approved pieces of music to be duly executed. "When I strike upon my musical stone," said his master musician Kuei, "the most ferocious wild beasts testify their joy; the people and the rulers are of one accord." To this day, every public ceremony has its appropriate air; and nothing is done by the emperor without some musical accompaniment. On the more remarkable occasions, such as the public audiences given by the emperor on his throne, they profess to perform some of the most ancient compositions, called Shao-yo, which were invented in the time of the Emperor Shun; and these are said to be tolerably soft and pleasing airs, not unlike the church music of Europe. But the Chinese themselves speak of their ancient harmony as now lost; and their modern performances, though sufficiently delightful in their ears, are represented by European travellers as wretched and discordant to an extreme. The ancient Chinese had only five tones, Kong, Shang, Keo, Tche, Yu, corresponding to the fa, sol, la, ut, re, of European nations; but under the dynasty of the Tcheoo, they afterwards added two semitones, Pien-kon and Pien-tche, equivalent to our mi and si.* This gamut of five whole notes and two semitones, resembling the natural scale of the Greeks, is marked by appropriate characters, like those of their written language; and by the help of these signs, or names of every note, they are able to write down a piece of music in a very clumsy stile; but they are ignorant of the mode of noting their tunes by means of spaces, lines, marks of the key, time, and expression. Several of these improvements they are said to have learned from the Jesuit missionary Pareira; but they discover no acquaintance with those scientific calculations and geometrical operations for perfecting the scale of notes, which the missionary writers have ascribed to the ancient musicians of China. They wander amidst flats and sharps without any fixed rule; and, in their transitions to a fourth or fifth, they run through all the intervening tones, semitones, and even quarter tones, in the most drawling manner possible. Though their bands occasionally attempt to play in unison, and an instrument among them is sometimes heard taking a higher or lower octave; yet it is affirmed, that they are wholly unable to play in parts, or to blend together several distinct melodies, so as form one concert of harmony. Their music, in short, is said to be altogether inconsistent, and incapable of being reduced to any certain rule; utterly unlike to that of any other existing nation; destitute also of any resemblance to the system of the ancient Greeks and Egyptians; and is either completely original, or a fragment of some style more ancient than any of those which are at present known.

---

* On the subject of Chinese music, see *Memoire sur la Musique des Anciens*, par Abbe Rousseau; and *Memoires Nouvelle sur la Chine*, tom. vi. par P. Amiot.

Music in China is neither learned as an accomplishment, nor practised as an amusement, by private individuals; but is the study only of those persons, who hire themselves for the entertainment of others, especially of those females, who are educated for sale, or addicted to prostitution.

Musical instruments.

Their musical instruments are sufficiently various, both as to their form and materials. They distinguish eight different kinds of sounds; and believe, that there are just as many sonorous bodies formed by nature, viz. the sound of skin, of stone, of metal, of baked earth, of silk, of wood, of the bamboo, and of a gourd.

Of the first class are drums, formed of boxes or barrels of baked earth or of wood, covered at both ends with the hide of some animal, generally the buffalo. Some of these drums are of a very large size, and when used, are placed on one end upon the ground, or upon stands resting on three or four feet, according to their size. Father Magalhens speaks of a drum at Pekin, which was forty feet in circumference.

Of the second class are the instruments called King, which consist of a number of sonorous stones of a siliceous nature, cut into the shape of a carpenter's square, and suspended by the angle in a wooden frame. Their tone is rendered flatter by diminishing their thickness, and sharper by taking from their length; and they are played by striking them with a rounded staff.

Of the third class are their bells, which are of various forms; sometimes round, occasionally flattened, and, in the lower part, resembling a crescent. They are composed generally of a mixture of tin and copper, and are sometimes of an enormous size. Father Magalhens describes one at Pekin, (which is used for announcing the hours of the night, and the sound of which is said to have an awfully solemn effect), as 13½ feet in diameter, 42 feet in circumference, 12 feet in height, and 50 tons in weight. Instruments are formed of 16 bells, properly assorted to correspond with the notes of the 16 sonorous stones, of which the King are composed. To this class belong also the different kinds of cymbals, and particularly the Loo or Gong, which is a kind of shallow kettle, with a flat rim raised about three inches, which is composed of a mixed metal of copper, tin, and bismuth, which is struck with a wooden mallet covered with leather, and which yields a shrill and piercing sound, heard at a very great distance.

Of the fourth class is the Hiuen, an instrument which the Chinese regard as of great antiquity, and which is a hollow piece of baked earth, about the size of a hen's or a goose's egg, and furnished with six holes to produce the notes, and a seventh for the mouth of the player.

Of the fifth class are the Shee and Kin, which are also instruments of great antiquity, and which are a species of lyres with strings of silk. The latter has only seven strings, and is generally about five feet in length; while the former is about nine feet long, and is frequently furnished with strings to the number of 25. Upon these instruments they play with the finger or a small stick. There are also different kinds of guitars with two, three, or four strings, which are the favourite instruments of the men; and a kind of violin, with two strings of different tones, between which the bow is made to pass, and the sound of which is described as peculiarly grating to an European ear.

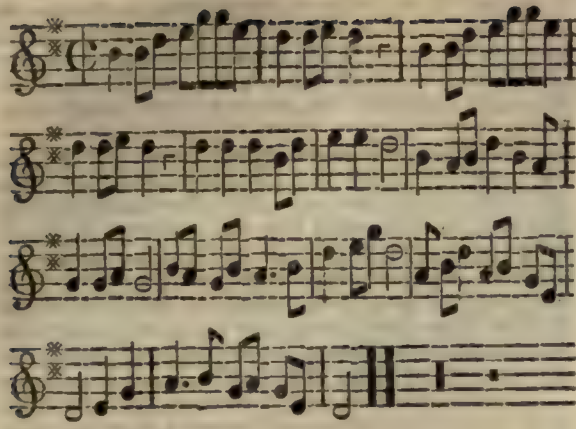
Of the sixth class are the wooden instruments called Tchoo, Yu, and Tchoong-too; the first of which is shaped like a bushel, and is struck with a hammer on the inside; the second is the figure of a tyger in a squatting position, and constructed in such a manner as to emit a sound, when gently scraped on the back with a rod; and the third consists of twelve pieces of wood tied together, which are used for beating time by holding them in the right hand, and striking them against the palm of the left. There are also hollow wooden instruments shaped like a fish, about 2½ feet in length, and six inches in breadth, which are much used by the soldiers in some provinces, and by the bonzes at their devotions, and which are struck with a loaded stick while they rest upon a kind of cushion.

Of the seventh class are the various kinds of flutes and pipes, which are chiefly used by the women; the most common of which has ten holes, and is extremely shrill and piercing. Others may be called trumpets, sometimes without holes, and sometimes with five or eight, and not unlike the French clarionets; the sound of which is exceedingly monotonous and disagreeable to the ears of an European.

Of the eighth class is the Sheng or Sing, one of the most agreeable of the Chinese instruments, which is a species of organ or rather Pan's-pipe, composed of a number of unequal bamboo reeds fixed into the lower half of a gourd, and furnished with a pipe on one side, shaped like the neck of a goose, to which the mouth of the player is applied, and which conveys the air to all the other reeds. The sounds, which it produces, are said to be sufficiently pleasing, but so wild and irregular as to be incapable of being reduced to any scale.

All these musical instruments are exceedingly imperfect, and are managed with very little taste or skill. The excellence of a performance seems to consist, in the opinion of the Chinese, in the greatness of the noise, produced by a confused union of different instruments; and the chief merit of the individual performers, in their musical bands, seems to consist in striking their drums, gongs, and cymbals with the utmost rapidity and vigour.

Their vocal music is more soft and pleasing; but the sounds are often forced through the throat and nose, in a very singular and indescribable manner. Their strain of singing is rather querulous and plaintive, yet seldom expressive of much feeling. There is commonly some accompaniment by a guitar; and the following favourite air of the Moo-lee-wha, from Mr Barrow, may be given as a specimen:—



AGRICULTURE.

Land holders.

Scarcities.

It is the great maxim of the Chinese government, that agriculture is the true source of national prosperity and wealth; and they have, in every period of their history, been forward to bestow the highest honours upon the improvers of this art. The husbandman holds the next rank to men of letters, and the officers of state; and both priests and soldiers are busily employed in the cultivation of the soil. Besides the annual ceremony of the emperor's commencing the labours of the season, at the vernal equinox, the first characters in the empire glory in giving their countenance and aid to the pursuits of husbandry; and, by the honour thus openly and universally testified for the occupations of the labouring classes, a most powerful and permanent impulse is given to their exertions. The emperor is regarded as the sole proprietor of the soil; and the holder of a landed estate pays as rent to the sovereign one-tenth of what his ground is supposed capable of producing. Though he be thus in reality, therefore, a tenant at will, yet he is never deprived of his possession, as long as he continues to pay his rent, or rather land-tax to the crown; and the Chinese cultivators regard their farms in no other light than personal property, as long as they find means to pay the public assessments. These holders of lands from the crown resemble European proprietors in this respect, also, that they can let what portion of their grounds they please, to others, for a rent which is generally equal to half the produce; and it is on these terms, that the great body of the Chinese peasantry cultivate their little farms. There is thus a pretty equal division of the lands among the growers of grain; and there are no immense farmers or monopolizers of produce, who can command the market. There is no ground set apart for the pleasure of individuals, but all is open to cultivation, and a free sale permitted to every dealer. There are no restrictions either from fishing upon the rivers, coasts, and lakes, or from killing game upon their own lands, and the public commons. Yet, with all these encouragements to the agriculturists, and notwithstanding all the honour attached to their occupation, they are not able to supply the wants of the nation; and seldom do three years elapse in succession, without a famine in one or other of the provinces. This frequent recurrence of scarcity may no doubt be partly ascribed to the circumstance of China being surrounded by mountainous and barren countries, from which it can draw no provisions in an unfruitful season, but which it is rather obliged occasionally to supply; to the want of foreign commerce, which prevents the importation of grain in the event of deficiencies; to the destruction frequently occasioned to the crops by droughts or inundations; to the great quantity of grain, especially of rice, which, in spite of the existing laws, is daily employed in the distillation of rack, and other spiritous liquors. But the principal cause of these scarcities is to be sought in the immense tracts of lands, which are suffered to lie waste, and in the want ef enterprize and skill in the Chinese cultivators. It is generally imagined, that every spot of ground in the empire is in a state of regular tillage; and then it is made a matter to be accounted for, how famines should be so very frequent. We read in many of the accounts of China, of the wonderful fertility of its soil; of the care of the husbandman to root out every hedge or tree, so that not a foot of ground may be lost; of the very mountain-sides being cut into terraces, like those of the *Pays de Vaud*, between Lausanne and Vevay, and covered with produce. All this, indeed, is strictly the fact in the immediate neighbourhood of towns and villages; but, partly from the dread of plunderers, and partly from the want of cattle to transport the manure and the produce, the more distant lands are almost entirely useless and unproductive; and it is calculated, that one-fourth of the whole country consists of lakes and swamps, which are totally uncultivated. On each side of the river Pei-ho, at no great distance from the capital, the gentlemen of the British embassy perceived no appearance of great cultivation. The greater part of the land was sour swampy ground, covered with coarse grass, rushes, and reeds; and few trees were to be seen, except in the vicinity of the villages. No habitation appeared, that could be considered as the residence of a gentleman, or even as a comfortable farm-house; but every thing, on the contrary, seemed to indicate the greatest poverty and meanness of condition in the inhabitants. The property of all this waste land is vested in the crown; but any individual, upon giving notice to the proper magistrate, may obtain whatever portion he chooses as a possession, by merely paying into the public granaries the estimated part of the produce, as rent to the government. But, owing to the poverty and ignorance of the yeomanry and peasantry, they can neither bear the expence of breaking up waste lands, nor execute the draining which these wet grounds require. Thus a considerable portion of the richest soil is entirely lost to the community; and the little spots of ground, which each individual husbandman occupies, seldom yields more produce than pays his rent, and supplies his family. The Chinese cultivators, also, though abundantly industrious, are extremely deficient in agricultural skill; and it may be said of them, in general, that they are rather gardeners, than farmers. One of their peasants, indeed, with as much land as he and his family are able to work with the spade, will raise a much greater quantity of food from that spot, than any European could produce; but if 50 or 100 acres of the best soil were assigned to him as a farm, he would scarcely draw from it even the moderate rent required.

Implements of husbandry.

Their instruments of tillage are extremely defective; and their common plough, which is of the most simple construction, dragged by a single buffalo, and far inferior to the worst in England, seldom opens the ground to the depth of four inches, in the best and deepest soils. Thus they never turn up new earth, and, though they were in possession of more effective instruments, their asses and mules would not be able to perform the work. The plough is composed of a single piece of crooked timber, the lower extremity of which is armed with the sock, and the superior is guided by the hand of the husbandman; while a perpendicular piece of wood rises from the middle of the beam, across the top of which another piece is placed lengthwise, one end of which is fixed to the handle, while the other is connected with the traces. The harrows are of different forms, according as the clods are of a greater or smaller size; but the kind, which is commonly used to smooth the surface, is very flat, composed of planks joined closely together, and armed with three rows of teeth. Upon this instrument the labourer places himself, and directs the buffalo which drags it, by a cord attached to a ring passing through the nostrils of the animal.

Mode of cropping

The Chinese farmer never suffers his ground to remain in fallow; and yet frequently raises from it two crops in the season. In the southern provinces, they procure two crops of rice, sowing the second as soon as the first is gathered. Sometimes, after a crop of cotton or indigo, they sow the field with wheat, which is ready to be cut in the months of May or June in the following year. Sometimes, they plant a row of beans between the drills of wheat, which ripen after the wheat is cut down; and their second crops are generally, lentils, beans, sweet potatoes, salads, or yams.

Manure.

The soil, which is generally loose, sandy, free from stones, and easily laboured, requires much manure, which is extremely scarce in the country, as very few domestic animals, and scarcely any sheep or cattle, are reared by the farmer. In the northern provinces, indeed, where horned cattle are more numerous, the husbandman is supplied with dung as in Europe; but, even in these quarters, the cattle are not provisioned in such a manner as to produce much manure. As the Chinese make little use of milk or butter, they are not careful to supply their cows with green food. They do not cultivate any of the artificial grasses; but feed their cattle chiefly on chaff and straw during winter, and in summer upon the rank natural herbage, which grow in the ditches, or on the common reeds, which cover large tracts of swampy grounds in many districts. In this dearth of manure, they make great use of composts, in which the principal ingredient is human ordure. This and other excrements are collected with great care, wherever they can be found. Large earthen jars are sunk in the ground around the houses for collecting urine, and every kind of putrid matter. The old men and children about the villages may be seen going their rounds, with rakes and baskets, gathering filth of every description. The slime and mud is dragged up from the bottom of the rivers and canals, and is particularly applied as manure to the cotton fields. The companies of soldiers and porters, who occasionally stop on their route for necessary purposes, are faithfully attended to their places of retirement by these dung-hunters. The barbers even carry a small bag along with them, to collect the hair, which they shave from the heads and faces of their customers, and which is accounted a very useful manure. Lime, burnt bones, decayed wood, putrid plants, and every similar substance, are carefully collected for the same purpose. All these various excrementitious and putrid matters are thrown into large holes in the fields, lined with cement; reduced almost to a liquid state by the addition of urine or water; and then poured, rather than spread, upon the soil. Manure is even considered as an article of commerce, and is transported in different forms to considerable distances. Boats of a particular construction, and filled with every species of ordure, may be seen passing along the rivers and canals; and their cargoes are sometimes made up in sufficiently curious shapes. "Among the different commodities for the supply of the capital," says Mr Barrow, "we observed an article of commerce that puzzled us not a little to find out for what it was intended. It consisted of dry brown cakes, not much larger but thicker than those we call crumpets. A close examination, however, soon discovered the nature of their composition, which, it seemed, was a mixture of every kind of filth and excrementitious substances, moulded into their present shape, and dried in the sun. In this form, they are carried to the capital, as articles of merchandize, where they meet with a ready market from the gardeners in the vicinity; who, after dissolving them in urine, use them for manure." In order to compensate for this deficiency of manure, the Chinese farmers are incessantly employed in working the soil and mixing it with extraneous matters, such as marl and stiff clay in light sandy grounds, and gravel or sand in strong clayey soils.

Grains cultivated.

The most prevailing crop in China is rice, especially in the southern provinces, and wherever there is a sufficient command of water. Next to rice, barley is most generally cultivated; wheat is very common, particularly in the northern districts; and the other grains are buck-wheat, millet, maize, peas and beans. The principal plants and shrubs cultivated as crops, are the sugar-cane, cotton, hemp, lint, tobacco, indigo, the tea-tree, the mulberry-tree, the varnish-tree, the camphor-tree, the tallow-tree, the cinnamon-tree, &c. In the fields also are cultivated a variety of pot-herbs, particularly a plant called pe-tsai, which is a species of beet, carrots, which are remarkably large, radishes, turnips, mustard, earthen pistachios, yams, and sweet potatoes.

Season and manner of sowing.

The first crop of rice is generally sown in March, and the second in July, according to the rains. The rice, before being sown, is steeped in pure water; the other grains in lime-water or urine, and this last is said to have the effect of preserving the seed, especially that of turnip, from insects. In the month of February, according to the observations of M. De Guignes, the crops were appearing above ground. In March and April, the barley was well advanced, the sugar-cane a foot above the surface, the oil shrubs in flower and beginning to ripen, and the hemp above a foot and a half in height; but the tallow and mulberry trees, at the same period, were scarcely in leaf.

In small patches of ground near the houses, where they study great neatness, the grain is often planted by dibbling; generally however by drilling, as a more expeditious method; and rarely by broad cast, which is neither so saving of the seed, nor so well suited for the clearing away of weeds. In sowing rice, they sometimes prepare a portion of ground as a seed-bed, which they cover with the grain in the broad-cast manner of sowing, and, when the plants have risen to the height of six or seven inches, they transplant them in rows into a field, which has been well levelled and watered. According to another method, the soil is well prepared and moistened, and the rice planted by the dibble in holes at the distance of six or seven inches from each other, into each of which several grains are put; but this plan requires a better soil, and consumes a greater quantity of seed. Sometimes, wheat is planted in the same manner. In some of the northern provinces, a sowing machine is used in the lighter soils, which is guided by two labourers, and which opens the drill and drops the seed at the same time. Great care is used to clean the crops of rice from weeds, and to supply them with water; and sometimes they sprinkle powdered lime over the plants, to destroy the vermin, and to render them more productive.

The stalks of the rice, wheat, and barley, seldom

Agriculture.

Harvest and produce.

grow to a greater height than three feet; but the straw of millet is commonly about five feet in length. The crops, in the middle provinces, are generally ripe in the beginning of June, and in the southern districts, are sometimes cut in April or May. The rice is ordinarily reaped three months after being planted; and its produce is generally from twenty-five to thirty for one, while that of the other grains is commonly from ten to fifteen for one. The corns, when reaped, are put up in small ricks, till they can be conveniently thrashed; but sometimes, especially in the northern provinces, where the sky is remarkably free from clouds in the autumn season, the grain is thrashed in the fields as soon as it is cut. This is done by beating the ear against the edge of a plank, or by treading it with oxen and buffaloes, or by passing over it cylinders of stone, or by flails in the hand as in Europe. The part of the flail which strikes the grain is sometimes composed of two pieces of wood; and is fixed to the handle, not by a piece of leather or skin, so as to turn easily any way, but by a small peg, which allows it to move only in a vertical direction. Besides the rice of a white colour, there is an inferior kind, of a reddish hue, which is eaten by the lower classes, or employed in distillation. The Chinese never cultivate oats, which would grow well in their fields, but which they pull up as a useless plant. Their horses are fed with cut straw and beans, or with natural grass. Their draught cattle are oxen, buffaloes, asses, and mules; but all these are, every where, except in the northern provinces, extremely rare; and no means are used for improving the breed of any domestic animal.

Gardening.

The Chinese excel in gardening, more than in agriculture; and have the talent of rendering a small spot productive in the highest degree. They confine their attention, however, principally to the quantity of vegetable produce, and are little acquainted with the means of improving the quality of their fruits, and hastening the growth of plants by the exclusion of cold air, by the admission of the sun's rays through glass covers, or by the application of artificial heat. Their oranges, and other native fruits, are naturally good, without much attention on the part of the gardener; but the European fruits raised in the country, namely, apples, pears, peaches, apricots and plums, are very indifferent. Their method of propagating fruit trees is curious, and may be worthy of notice. In the spring season, they strip a ring of bark, about an inch wide, from a bearing branch; surround the place with a ball of fat earth or loam, binding it fast with a piece of matting; and suspend directly above it a pot or horn full of water, with a small hole in its lower part, sufficient to let the water drop in such quantities, as to keep the earth constantly and uniformly moist. The branch, when treated in this manner, throws out new roots into the ball of earth just above the ring, from which the bark was taken; and, if sawn off and planted at the fall of the leaf, it bears fruit the following summer.

Method of propagating fruit trees.

Embellishments of gardens.

The Chinese are particularly eminent in the art of embellishing garden grounds, which may be considered as the only one of the fine arts, in which they display either genius or taste. In this department, they are said to have attained a high degree of perfection; and to possess the most striking and distinct conceptions of picturesque beauty. There is supposed to be a great resemblance between the English and the Chinese style of gardening; except, that the excellence of the former consists rather in improving, and that of the latter in conquering nature. The object of a Chinese planner is to change every thing from the state in which he finds it; and he is therefore little anxious about the natural advantages of the spot, which he chooses as the scene of his operations. "If there be a waste," says Lord Macartney, "he adorns it with trees; if a dry desert, he waters it with a river, or floats it with a lake. If there be a small flat, he varies it with all possible conversions; he undulates the surface, he raises it with hills, he scoops it into vallies, he roughens it with rocks." They require only a good exposure, a salubrious atmosphere, and a retired situation; and then they set themselves to collect, in that one spot, all the most interesting and picturesque objects, which an extensive tract of country could furnish. Their great object is to bring together under one view the cultivated field and the barren waste, and they particularly exert themselves to render the surface uneven; to cover it with factitious rocks, to dig caverns and narrow passages along the sides of the eminences; to cover some of these little hills with wood, and to leave others completely naked; to plant their trees in the utmost irregularity, as if dropped by chance, and to open, amidst all this apparent disorder, a number of winding paths, which perpetually approach each other, without even uniting, and which seem to prolong the extent of the scene, without any termination. If water can be procured, it is precipitated from the heights, made to open for itself a passage among the rocks, conducted through the grounds in various directions, and at length collected in a lake, upon which the ladies, in barks of an elegant construction, amuse themselves with sailing, fishing, and enjoying the freshness of the fragrant air. These lakes are covered with leaves and flowers of their large and beautiful water plants; stored with a multitude of little shining fishes; studded with islands, ornamented with pavilions, triumphal arches and pagodas; and bordered with rugged stones, which communicate a romantic irregularity to their form and aspect, or with a shade of weeping willows hanging over a beach of shells and sand. The general defect of these scenes is the confusion, created by such a multitude of different objects, crowded within a narrow space; and one instance of bad taste, from which none of them is exempt, appears in the large porcelain figures of lions, tygers, &c. which are scattered about in the greatest profusion.

Imperial gardens.

The most magnificent and extensive of the emperor's gardens are those of Yuen-min yuen at Pekin, and of Gehol in Tartary; the latter of which is admirably described by Lord Macartney,* who compares the western part of it to Lowther hall in Westmoreland. The former comprehends an extent of ground, not less than ten English miles in diameter, or about 60,000 acres; and contains, within its inclosure, thirty separate habitations for the emperor, each of them composing a village of considerable magnitude. Much of it is waste or woodland; and the general aspect of some parts of it is likened to that of Richmond. The trees, in some places, are so carefully arranged with respect to their figure and foliage, as to present a most beautiful landscape; while its numerous canals, rivers and lakes, are disposed in so irregular a style, as to have more the appearance of a natural origin, than of an artificial construction.

POPULATION.

The population of China has been a subject of much calculation and of keen dispute among all who have written upon the state of that empire; and there are still no sufficiently authentic documents, from which its amount can be satisfactorily ascertained. The statements of the French missionaries refer to so many different periods, are founded so much upon mere conjectural computations, and are attended with so many irreconcileable discrepancies, that it is impossible to frame a consistent view of the matter from the varying data, which they severally furnish. The inhabitants of China, for instance, have been calculated

* Barrow's *Travels in China*, p. 126.

In 1122	at	46.734,784
In 1290	at	58.834,711
In 1650	at	105.871,434
In 1662	at	115,052,724
In 1736	at	117.967,745
In 1743	at	150,265,475
In 1760	at	196,837,977
In 1761	at	198,214.553
In 1794	at	333,000,000*

The following table presents three of these statements in a more detailed form; and may enable our readers, by a comparative view of their variations, to detect more easily, and to ascertain more clearly, their complete inconsistency. The statement for the year 1743, is founded upon the report of the French missionaries; that for 1761, upon the authority chiefly of Father Allerstain; and that for 1794, upon the accounts of the British embassy.

Provinces.	1743.	1761.	1794.
Pe-tchelee .	16,702,765	15,222,940	38.000,000
Kiang-nan .	26,766,365	45,922,420	32,000,000
Kiang-see .	6,681,350	11,006,640	19,000,000
Tche-kiang	15,628,990	15,429,690	21,000,000
Fo-kien . .	7,643,035	8,063,671	15,000,000
Hoo-quang	4,264,850	16,909,923	27,000,000
Ho-nan . .	12,637,280	16,332,507	25,000,000
Shan-tong .	12,159,680	25,180,734	24,000,000
Shan-see . .	8,969,475	9,768,189	27,000,000
Shen-see . .	14,804,035	14.699,475	30,000,000
Se-tchuen .	15,181,710	2,782,976	27,000,000
Quang-tong	6,006,600	6,797,597	21,000,000
Quan-see .	1,143,450	3,947,414	10,000,000
Yun-nan . .	1,189,825	2,078,802	8,000,000
Koei-tchoo .	255,445	3,402,722	9,000,000
Leao-tong .	235,620	668,852	10,000,000
	150,265,475	198,214,552	343,000,000

The last of these statements, which makes the population of China amount to 333,000,000, omitting Leao-tong, was communicated to the British embassy by the principal Chinese officers of state; and Mr Barrow, though ready to acknowledge the little dependence which can be placed upon their authority, endeavours, with considerable ingenuity, to prove at least the possibility of its truth. If China contains 1,297,999 square miles, there would thus, upon an average, be 256 souls to every square mile, which is not much more than twice the proportion which is found to exist in Great Britain. The united provinces of Holland have been calculated to contain 270 inhabitants upon every square mile; and the island of Barbadoes, which is said to have contained, in 1670, a proportion of 500, is ascertained, by a more accurate enumeration in 1786, to support at least 263 inhabitants upon each square mile. Hence it is argued, that China may be conceived, without any great stretch of belief, to maintain the number assigned above, especially when it is considered, that it enjoys advantages favourable to population beyond most other countries in the world. In support of this opinion, it is alleged, that, excepting a few skirmishes on the frontiers with the Russians and Indians, it has enjoyed a profound peace since the Tartar conquest; that, as its soldiers are parcelled out as guards in the towns, cities, villages, and stations upon the roads and canals, where they have portions of land allotted for their use, they all enter into the married state; that, as the nation has little foreign commerce, there are few seamen in proportion, and that those who belong to the inland navigation are generally the fathers of families; that celibacy is, by public opinion, regarded as discreditable, and, after a certain time of life, is actually marked with infamy; that every male child may secure a subsistence from the moment of its birth, by being enrolled in the military list; that there are few of those large manufactures and mechanical occupations in crowded cities, which, in other countries, prove so destructive to health and population, by the debaucheries and diseases which they occasion; that, by the equal division of the soil into small farms, every peasant possesses the means of bringing up his family, while the great body of the people are also, from the same cause, employed in active and wholesome labour in the open air; that the lower orders, partly from their poverty, are temperate in their mode of living, and little addicted to the vice of drunkenness; that the climate is moderate and uniform, and that, excepting the small-pox and other contagious disorders, which occasionally break out in their more confined and crowded cities, there are few epidemical distempers in the country; that no superfluous animals are kept for pleasure, and even very few for labour, so that the whole cultivated surface is applied almost solely to the production of food for human beings; that the people abstain almost entirely from animal food, except those kinds which are most easily reared, such as pigs and poultry, and live almost wholly upon grain, viz. rice, which yields an immense increase, and of which they can often raise two crops in the year; that the carriage of goods from place to place is performed, not by unproductive highways, but by canals, rivers, and lakes, abounding in fish, and thus affording subsistence to a considerable portion of the natives.† From all these considerations it is conceived, that the population of China may not only amount to the highest statement which has yet been given, but that it is even scarcely equal to the means of subsistence which the country is capable of yielding; and that, were a more efficient plan of cultivation introduced, especially if the more sure crops of potatoes in the northern parts, and of Guinea corn in the south, were substituted for the precarious culture of rice, a still greater quantity of nourishment might be produced, and a still greater number of inhabitants supported.

Causes of its immense population.

Objections to his statement.

On the other hand, M. De Guignes, a more recent traveller in China, and who resided a much longer pe-

---

* One very obvious remark, upon these accounts, is this, that if they are founded in truth, then the empire of China, instead of having continued nearly in its present state of civilization and prosperity, for the space of 2000 years, appears rather like a newly established country, increasing rapidly in wealth and population.

† In one day, the British embassy passed, upon the river Pei-ho, more than 600 large vessels, having each a range of ten or twelve distinct apartments built upon their decks, and each apartment containing a whole family; so that each vessel was calculated to lodge about fifty individuals; and reckoning the other kinds of craft passing and repassing, or chained to the banks, and crowded with women and children, they calculated, that, in a space of ninety miles, there were floating on this small branch not fewer than 100,000 souls.

Population.

Population.

riod in the country, decidedly controverts the fact of an immense population in the Chinese empire; and maintains, upon very positive grounds, that it does not much exceed that of other countries, in proportion to the extent of territory.

In this view, he considers, first of all, the presumptive arguments against so immense a population, from the present state of China in respect of cultivation; from the fact of one-third (Mr Barrow himself admits one-fourth) of the soil being altogether unproductive, a point which he fully establishes from the accounts of those missionaries who had traversed the different provinces; from the peculiarity of its situation with regard to the adjoining countries, which are utterly unable to afford any supplies of provisions; and from the frequent failures in its actual produce, and the famines consequent upon such calamities, which have been uniformly presenting the most effectual checks to an increase of population. Thus defective in its own cultivation, and thus unable to procure supplies from other countries, it cannot be presumed to subsist a proportionable number of inhabitants with such nations as Great Britain and the United Provinces, which, in addition to their improved agriculture, import so abundantly from the most distant parts of the globe.

He next examines the statements of Chinese population as actually given, and remarks upon the internal evidence, which they afford, of inaccuracy and uncertainty. In the first period of eighteen years, from 1743 to 1761, according to the preceding table, the province of Pe-tchelee declined in the number of its inhabitants, while, in the next thirty-three years, from 1761 to 1794, it was more than doubled. In the first period, on the contrary, Kiang-nan nearly doubled its population, while, in the second, it declined more than one-fourth. Hoo-quang, in the first eighteen years, increased almost fourfold; while Se-tchuen, in the same period, sunk from fifteen millions to two, and, in the next thirty-three years, rose from two to twenty-seven millions. Koei-tcheoo again, in eighteen years, increased to thirteen times its number; and Leao-tong, in thirty-three years, nearly fifteen times. The very assertion of such progress in a country, which is acknowledged to have been stationary, in point of improvement, for many hundreds of years, is itself a circumstance sufficiently suspicious. In the statement given to the British embassy, the uniform use of round numbers is considered as a sufficient evidence of its inaccuracy, and of its having been founded rather upon conjecture than any actual survey; while it bears other notorious marks of incorrectness and exaggeration. The province of Pe-tchelee, for instance, is represented as more populous than that of Kiang-nan, though it is one-half less in point of extent, and neither so fertile in its soil, nor so full of manufactures. Kiang-nan again, which contains about 10,000 square leagues, is rated at a population nearly one-third, according to the statement of the British embassy, and nearly one-half, according to Father Allerstain's account, greater than that of France before the revolution, a country three times more extensive in point of territory. Such amazing variations cannot be accounted for by the supposition of migrations among the natives from one province to another; as it is known, that, from the poverty, superstitions, and agricultural occupations of the Chinese, there is no nation in the world less apt to remove from place to place. The great diminutions in the population of the different provinces, may easily, indeed, be conceived to have been occasioned by those dreadful famines, which not unfrequently occur in this extensive empire, and which often reduce the inhabitants of a district, to one-half their number; but nothing, in the condition and customs of the Chinese, can explain those speedy and extraordinary augmentations, which the above statements bear.

It is admitted on all hands, even by those who are inclined to credit the highest accounts of the population of China, that no dependence can be placed upon the statements of the Chinese themselves, whose government, says Mr Barrow, "is much given to exaggeration in all matters relating to the aggrandisement of their country, and to deal liberally in hyperboles when numbers are concerned." "No people in the world," says M. De Guignes, "are more disposed to exaggerate every circumstance relating to their own country. They make no scruple whatever to deceive a foreigner, as it gratifies their vanity, and increases their own importance, to overrate the power of their nation." Full credit cannot be given even to those statements, which are drawn from the official papers and most authentic documents of the government itself; because it is the interest of the mandarins to represent the population as always increasing, that the provinces may appear to have improved under their administration; while it would displease the sovereign, and obstruct their own advancement, were they to announce the smallest diminution. Now, as these viceroys are changed every two or three years, and as every one has an equal interest in making these flattering representations, it may easily be conceived how rapidly the population of the empire increases upon the face of the state papers.

It is chiefly, then, from the observations of those who have travelled in the country, that any reasonable opinion can be formed respecting, at least, the relative population of China. There, indeed, also, the accounts are rather discordant; but the majority of recent testimonies decidedly tend to prove, that this boasted empire is not more populous, than other civilized or established countries. Mr Barrow speaks in general, in the most positive terms, of the great population of the different places, through which the British embassy were made to pass; and he insists, that the immense crowds of people, whom they witnessed, were not confined to the larger towns, and the places at which they halted in their progress; but that some of those parts, which were at a distance from the common road, were found to be the most populous of any in their route. This assertion seems to be completely neutralized by his own testimony, in another part of his work, where he expressly says, "the proximity of the capital would have led one to expect a corresponding population. Nothing of this kind appeared. The vast numbers we had observed in ascending the river, were drawn from the distance of many miles out of mere curiosity. The inhabitants only of the vicinity now shewed themselves, and we were rather surprised at the fewness of these, as well as at the very ruinous and miserable condition of almost all the cottages." By the journal of a gentleman in the train of the Dutch embassy, which is cited in the travels of Mr Barrow, we learn, that they were surprised to find so few cities, towns, and villages in their route; that sometimes not a single dwelling, or trace of cultivation, was seen in a space of eight or ten English miles; that many of the habitations, which they did perceive, were in the most ruinous condition imaginable, and that one of the party declared, he did not believe the whole world could furnish such a picture of desolation and misery, as they witnessed.

M. De Guignes enters more fully into the subject, and describes the appearance of the country, in the express view of fixing the degree of the population. We consider his opinion as decisive on this point; and submit to our readers the following extract from his work. "In our route to Pekin, as we ascended the river from Canton to Nan-hiong foo, the last city of the province, in the whole of this space, which is 105 leagues, we found only five cities, distant from each other 17, 19, 24, and 28 leagues. The population in the country was extremely moderate. It appeared to us a little more crowded in the towns. But the circumstance of our passing had collected a multitude upon the route; and when, upon our return, we visited the same places at our leisure, the inhabitants did not appear in greater numbers than in other quarters.

"The same was the case in Kiang-see. Except in two or three cities, to which our arrival had attracted the inhabitants of the surrounding country, the number of individuals was no way surprising. In traversing by water the greater part of this province, we found the cities at the distance of 12, 15, and 25 leagues, and afterwards of 11, 9, and 7 leagues from each other. There was only one at five, and another at three leagues interval. In short, we saw only twelve cities in a space of 116 leagues. When we quitted our barks, and travelled by land in Kiang-see and Hoo-kooang, in an interval of 40 leagues, we passed through four cities; and, as the route lay through the midst of fields, villages, and towns, it would have been easy for us to have satisfied ourselves, whether the inhabitants were very numerous; but nothing presented any proof of such a fact.

"In Kiang-nan, within the space of 118 leagues, we found only eight cities, at a distance from each other of 11, 12, 14, 18, and 21 leagues; and two of them at an interval of 5 and 4 leagues. With respect to this western part of Kiang-nan, there cannot be a moment's doubt respecting the degree of population: it is very moderate.

"Shan-tong presented us successively, in a space of 80 leagues, only with 10 cities, at distances of 22, 11, 9, 8, 6, and 5½ leagues.

"In Pe-tchelee, we found as many, a little nearer to each other, indeed, as we travelled only 63 leagues; but such cities! and above all, such villages! The greater part presented the afflicting spectacle of absolute devastation, while Pekin, in the midst of so many miserable objects, surrounded with vast walls, adorned with superb pavilions and magnificent palaces, seemed, if the expression may be allowed, to have sucked up and absorbed in itself the whole surrounding country.

"Upon leaving the capital upon our return, we pursued the same route as far as the city of Te-tcheoo, where we altered our course, in order to follow the eastern coast. In this new tract, we travelled 83 leagues in Shan-tong, and passed 8 cities, of which the three first, which were nearest to Pe-tchelee, were at the distance of 3 and of 4 leagues from each other; and the rest at a distance of 13, 14, 18, and 20 leagues, and only one at an interval of 7 leagues. The soil in this part of Shan-tong is not so bad as in the western part of the same province, and presented a more numerous, but still not a very crowded population."

"Having arrived at the eastern part of Kiang-see, the best portion of China, and which is always shewn by the Chinese to foreigners in preference to any other part, we found, in the vicinity of the dike which is raised along the banks of the Yellow river, towns which appeared to us extremely populous. It was from this population, that the English formed their opinion; and it was thus that they were led into an error. In passing through the same places as these travellers, I could have believed with them, that the number of inhabitants was considerable; but I discovered, that I would have been deceived, had I trusted to the first appearance. The advantage which we enjoyed of setting out at our own pleasure, afforded us the means of proving, that this population did not wholly belong to the places where we halted, but that a great proportion had been attracted thither from the neighbouring country. These towns, so populous at our arrival, presented almost a complete desert at the time when we took our departure; and we perceived, in the country, numerous bands of the inhabitants, who were returning to their villages.

"Though the part of Kiang-nan, which lies to the north of Hoang-ho, is good, yet in the space of 40 leagues we saw only two cities, at a distance of 24 and 15 leagues; and then three more, after having crossed that river, before coming to Tain-kiang-foo, on the north of the Kiang, that is to say, in a course of 28 leagues. The portion of Kiang-nan, after crossing the river Kiang, is beautiful and well peopled; the towns are closer to each other; and, in a space of 42 leagues, we found five cities at the distance of 4, 5, 7, 8, and 9 leagues from each other.

"Entering the province of Tche-kiang, we passed over 22 leagues without seeing one city; but, as the canals take a winding direction, we left upon one side a city of the first class, and another of the third; but still, reckoning these two cities, we only passed twelve in the 95 leagues which we travelled in this province, that is to say, one city at the distance of 4 leagues, two at 5, two at 7, one at 8, one at 9, two at 10, two at 11, and one at 12. The cantons of Tche-kiang, which border upon the province of Kiang-nan, and those which surround the city of Hang-tcheoo-foo, are well peopled; but, in ascending the river as far as the extremity of the province, the population is moderate, and the cities have nothing extraordinary, although, of the eight cities which we saw in this part of Tche-kiang, and which are at the distance of 11, 10, 9, 8, 7, and 4 leagues from each other, there are two of the first rank.

"We met few people on the road, which separates Tche-kiang from Kiang-see. Yu-shan-hien, the first city of this latter province, and which we had full time to examine, had only a population proportioned to its small extent. In descending the river to Nan-tchang-foo, the capital of Kiang-see, which was a route of 74 leagues, we passed by six cities, of which two were situated at a distance of 8 leagues, one at 10, one at 12, one at 16, and Nan-tchang-foo at 20. This capital where we halted is large, but its population did not appear to us extraordinary. We have thus had an opportunity, during a journey of near 1600 leagues, of judging whether the provinces of China were as populous as the English have advanced. I have made, in going to Pekin, pretty long journies without meeting a single person; and if, in my return, I saw a great number of people in certain places, still there was nothing to excite astonishment. In a word, nothing can induce me to believe, that the population in general is immense. I shall say only one word more. It is an error to suppose, that there exists in China a second population upon the rivers. Except the principal and commercial cities, in the neighbourhood of which a pretty large number of boats are found, there is only seen upon the rivers such a number of people as is suitable to a vast and extended country, the whole of whose commerce is carried on by water." *

---

* *Voyages a Pekin, &c.* par M. De Guignes, tom. iii. p. 80.

This author is decidedly of opinion, that the population of China cannot reasonably be estimated higher than 150,000,000; and that even this number is considerably above the truth, as it makes that country in proportion to its extent rather more populous than France, while this latter kingdom contains a greater proportion of cultivated soil.*

NAVIGATION.

Canals.

The inland navigation of China is inconceivably extensive; and in the construction and management of vessels for this purpose the Chinese have reached a very high degree of skill. The whole country is intersected by an infinite number of rivers and canals; which last have been multiplied to the utmost possible degree, not only with a view to water the fields, but also to open communications between different places, and to facilitate the conveyance of goods. The whole of the home trade is carried on by water; and even individuals, travelling from one town or province to another, uniformly, if possible, prefer the conveyance by boats to land carriages. In that way they can travel from Canton to Pekin without interruption, except one day's journey across the tract of land which separates Nan-hiong-foo from Nan-ngan-foo. After leaving this last mentioned city, the course leads down the river to the lake Po-yang, thence along the river Yang-tse-kiang to Kooa-tcheoo, beyond Nan-kin, where the imperial canal commences, and conducts the traveller all the way to Pekin.†

Canal boats.

To the construction of proper vessels for this inland conveyance of passengers and articles of traffic, the Chinese have directed their chief attention; and they are generally allowed to have succeeded beyond all other people, in the great variety and skilful adaptation of their boats to the different purposes for which they are employed, and the different courses of water through which they must pass. Many of them are remarkable for the stateliness and elegance of their form; and especially for the excellent accommodation, which they contain for the passengers who are on board.

Pleasure boats.

The most beautiful of these boats are those, which are intended for parties of pleasure upon the water, and which are generally of a considerable size, containing a small anti chamber, a large apartment in the middle, and a small cabin behind, all neatly furnished and provided with windows adorned with shell-work or lattices. These, and most of the other larger barks, have a projecting gang way of broad planks on each side, by which the crew can pass from one end to the other in working the vessel, without incommoding those who are on board. In calm weather, and when the wind or current is contrary, the vessels are dragged by a rope, or impelled by means of two large bamboo oars, turning upon pivots placed upon projecting pieces of wood, sometimes at the stern, as is usual with most other nations, but often also near to the bow of the vessel. From six to ten men are required to work one of these oars, which they move backwards and forwards in the water under the surface, similar to the English mode of *sailing*, and which they keep very near to the sides of the boat, so as not to interfere with other vessels, as they pass each other in the canals and rivers.

Boats for merchandize.

The boats, which are employed for transporting merchandize, are almost as much rounded above as below, and are covered partly with planks, partly with mats, which can be drawn aside at pleasure in loading and unloading. These barks are heavy and slow, and carry a very large sail; but do not sustain the wind well, unless when they are loaded. One of these vessels belonging to the revenue department, as measured by Mr Barrow, was 115 feet in length, 15 in breadth, and six deep; the sides straight, the width nearly the same fore and aft, and the whole shaped like a narrow trough.

Passage boats.

Next to these, the most numerous kind of vessels upon the rivers and canals are the yachts or passage boats, which are very lightly and neatly built, and are sometimes of a very considerable size, with high upper works, so as to resemble floating houses. Those of the larger class generally contain three apartments for the accommodation of passengers, an anti chamber for the servants and baggage, a commodious sitting or dining-room, about 15 feet square, and a space containing three or four sleeping-rooms. Behind these are the kitchen, and a set of small holes for the seamen. Sometimes there is a kind of second story, divided into little cells like coffins, in which a Chinese sailor, whose whole property is commonly upon his back, accommodates himself with great ease; while on each side is a projecting gang-way, as above described. These vessels are long, narrow, flat-bottomed, sometimes a little curved, and seldom draw above 15 inches water. In one place, the British embassy were conveyed in boats of this description, which were from 50 to 70 feet in length, moderately loaded; and which, nevertheless, did not draw above six inches water. In this way they sailed along a mere trout-stream; in the more shallow places of which a channel was made for the boats by removing the gravel with iron rakes.

Boats for mandarins.

The boats for the mandarins are not unlike the pleasure-boats, generally painted red, ornamented with figures of dragons and little flags.

The Chinese make use also of large rafts of bamboo for conveying wood and rice, and generally keep them on a level with the surface of the water.

Shipping.

In the navigation of the open sea, and in the construction of vessels for distant voyages, the Chinese are as awkward and unskilful, as they are ingenious and expert in the direction of the fresh water shipping.

Maritime intercourse.

It has been asserted, that their maritime knowledge was more extensive in ancient than it is in modern times; that, in the seventh century, they carried on a trade with the western coast of North America; and that at one period, they maintained a commercial intercourse with Bussora, Siraff, and other ports in the Persian Gulf. It is certain, that about the seventh century, they were acquainted with the promontory of Kamskatka by the name of Ta-shan; and it is considered as unquestionable, that the island of Tchoka in the Tartarian sea, opposite to the mouth of the Amour, has been peopled from China. They are supposed also to have colonized Sumatra, as there is a striking resemblance, in person and manners, between the inhabitants of that island and the natives of China; and the Cingalese are considered as still more decidedly descended from a Chinese stock. According to the accounts of the celebrated Italian traveller, Marco Polo, the Chinese must have been in the habit of visiting the island of Madagascar before his time; and it is asserted by Mr Barrow, as an obvious matter of fact, that many of the Hottentots strikingly resemble the Chinese in the form of their persons, in the features of their countenance, and in their manner of speaking, so as to render it highly probable, that those tribes on the narrow extremity of Africa, who differ so remarkably from all their neighbours, have derived their origin from a colony of Chinese, to whom they bear so close a resemblance. Even admitting, however, these marks of affinity between the natives of these different countries and the inhabitants of China, and the probable conclusion that they must have therefore derived their origin from some Chinese colony, there is still no proof of the existence of a regular and extended navigation from China to these quarters. On the contrary, it is affirmed as an acknowledged fact, that the Chinese mariners were not acquainted with the island of Formosa till the year 1430; nor with the isles of Pong-hoo till 1564; and hence it is not at all probable, that they should have been in the practice of frequenting distant coasts at a period when they had not explored the seas which wash their own shores.

---

* In the newspaper of the *Pilot*, for August 11, 1812, it is affirmed, that, according to a statistical survey, officially published and recorded in the Gazette of Pekin, (but where or by whom this document has been seen, we have not been able to discover,) the population of the Chinese empire is only about 55,000,000 of souls, which is far below the most moderate of the more recent computations. Perhaps, however, as is generally the case in the Chinese surveys, this number includes only those who are taxable; and multiplying it by 3, which M. De Guignes considers as the fair average of the number in each family in China, the result would be 165,000,000, which is not very different from the highest estimate, which this traveller allows to be at all founded on probable grounds.

† See this Canal described under the head of Architecture and Public Works.

Practical navigation.

Mariner's compass.

Their whole style of seamanship argues no established skill or extended practice. They have no idea of keeping any reckoning at sea, so as to ascertain by estimation of the distance sailed, or by observation of the heavenly bodies, the longitude and latitude of particular places. Their system is to keep as near to the shore as possible, and never to lose sight of land. In this way the commerce of the Yellow sea is carried on from port to port; and the articles of traffic pass through a multitude of hands, before they reach the consumer. When they do attempt more distant voyages to Japan, Batavia, Manilla, Cochinchina, and Borneo, they embrace a favourable monsoon; and if they know the direction of the port which they wish to make, they endeavour, whatever be the wind, always to keep the prow of the vessel pointing as exactly as possible to that particular quarter. They are generally admitted to have been acquainted with the polar direction of the load-stone, and to have employed it in navigation long before that important invention was known in Europe; and it is conjectured, that Marco Polo brought from China, about the end of the thirteenth century, this new and valuable use of the magnetic needle. But, however remote their acquaintance with this discovery may have been, and in whatever way they attained the knowledge of it, they have made little progress in its improvement; and their mariner's compass is to this day an extremely imperfect instrument. The needle is exceedingly diminutive in size, seldom above three-fourths of an inch in length, and so very fine, as well as short, that it does not require to be loaded at one end more than another to prevent its dipping towards the horizon. The card is divided into eight principal points, and each of these again is subdivided into three; while the needle is allowed to traverse the fixed points, instead of being attached to the card. They are utterly ignorant of the variation and inclination of the needle; and the box, in which it is placed, is extremely small, just sufficient to allow its vibration. The margin, however, of this box is frequently so large as to contain 20 or 30 concentric circles, marked with various characters, comprising an abstract of their astronomical science, especially the names of the 12 hours of the day, the 28 signs of the zodiac, the 24 subdivisions or seasons of the year, the cycle of 60 years, the names of certain constellations, with their positions in the heavens, the marks of the five elements, and the rules for calculating lucky and unlucky days. Behind the compass, is generally placed a small shrine or pagoda, with an altar before it, on which a spiral taper of wax, tallow, or sandal wood dust is kept continually burning. This seems to be intended both as an act of devotion and a measure of time; for this taper is divided into 12 equal parts, and proportioned in such a manner, that the whole is consumed in a complete day. It would appear also, that they regard the magnetic needle as a species of divinity, or at least as under the protection of some superior being; as, upon every appearance of a change of weather, they burn incense before the compass. The box, which contains it, is not suspended, but generally placed in a vessel full of sand; in which, when they have no shrine, are stuck little candles of scented wood, or merely slips of bamboo, with a little sandal wood dust on one end.

Trading vessels.

Masts.

Sails.

Rudder.

Anchors.

The construction of their trading vessels, intended for distant seas, is extremely unfavourable; and it is considered as a matter of wonder, how they are able, even with the aid of the compass, to reach the ports of Batavia in such clumsy and unmanageable shipping. These merchantmen are called by the Portuguese, Soma or Sommes; and by the Chinese, Tchuan, which last appellation the British seamen have corrupted into Junks. The general form of the hull, or body of the ship, as seen above water, is like the appearance of the moon, when four days old, as the two extremities rise to a great height above the deck. The bow or forepart is not rounded, as in the vessels of Europe, but square and flat, like the stern, without any of the projecting wood called cut-water, or any kind of keel. In the front is frequently carved the open mouth of a dragon; but on each side of the bow, is generally painted also a large circular eye, supposed to be an imitation of that of a fish. There is no bow-sprit; but there are two, three, and often four masts, each of which consists of a single piece of wood, incapable of being reduced in length, not less in diameter, in the larger traders, than those of a British 64; and fixed in beds of massive tin, laid across the deck. Each mast has a single sail of bamboo matting, stretched by means of bamboo poles, running across at the distance of two feet from each other; and constructed in such a manner, that the sail can be folded together like a screen, or furled like a fan. These sails are extremely heavy, and difficult to be extended or lowered; and in the former operation, a kind of machinery is frequently employed; and, in the latter, a sailor ascends the mast, and pushes down the sail with his feet. Hence, the Chinese seamen are very reluctant to lower their sails, even when the safety of the ship requires that precaution; and many of their vessels are upset by the mere quantity of sail which they keep up in blowing weather. When these large sails are hoisted, and braced almost parallel with the sides of the ship, a Chinese junk will run within four and three points, or even sometimes half a point of the wind; but this advantage is greatly counteracted by their want of keel and their rounded bottom, which cause them to drift much to leeward. The rudder is placed in a large opening in the stern, and is fastened chiefly by means of cables, so that it can be occasionally taken up to avoid sands and shallows; but its power is thus greatly diminished by the constant slackening of the ropes, which connect it with the ship. Their anchors are made of a hard and heavy kind of wood, called Tie-moo, *iron-wood*, which they consider as less apt to bend than those which are made of iron; but, in

Pitch. **Hold.** **Size and tonnage.**

general, their extremities are pointed with that metal. Instead of pitch, the Chinese use a kind of gum or oil, called Tong-Yeoo, mixed with lime and threads of bamboo, a composition which hardens in the water, and becomes completely impenetrable; so that a well or two in the hold, or even one only below the main-mast, and which they empty with buckets, instead of pumps, is sufficient to keep the ship perfectly dry. The hold is divided into a number of smaller holds or spaces, with partitions of plank three inches thick, and so carefully cauked with the above mentioned gum, that no water can pass from the one to the other. This plan is attended with obvious benefit in the event of a leak appearing, as the water is thus confined to the particular apartments in which the injury has been sustained; and it might be adopted with advantage by other nations, especially in these vessels, which are designed for distant voyages. These Chinese merchantmen, according to Grosier, are seldom above 90 feet long; but, according to Osbeck, sometimes 200; according to Grosier, seldom above 300 tons burden; according to De Guignes, they are often 600 tons; and Mr Barrow speaks of them as sometimes carrying 1000 tons, with a crew of 500 men. A vessel of this size frequently belongs to 50 or even 100 merchants; and is divided into as many compartments as there are partners. Each of these partners ships his goods in his own birth, which he fits up according to his pleasure; and either goes himself, or sends a son or other relative to take the charge of them. These ships of the Chinese seldom draw as many feet of water, as those of Europe draw fathoms; and are particularly adapted in this respect for the shallow seas, which wash the eastern coast of China.

Ships of war.

The Chinese ships of war are constructed in a similar manner with the trading vessels, except that the two ends are less elevated above the level of the deck, and that the bottom is more narrow. They carry strong carabines and small cannon, and have their port-holes extremely contracted. The soldiers on board are armed also with lances and bucklers, and are frequently protected by a parapet of bamboo along the sides of the vessel. Some of the government galleys have sharp prows; and one kind, which is called *a hawk's bill*, is equally pointed at the stern as at the bow, so that it can advance or retreat without putting about. None but the ships of war are permitted to carry arms; and the traders, when attacked by pirates, have no other means of defence, but stones or sharp-pointed poles of bamboo.

Fishing boats.

Their fishing boats, of the larger class, are peculiarly excellent, and sail in a superior style. They are strongly built, furnished with decks, and can each accommodate eight or ten fishers, with their wives and children. They generally sail two of them in company; and, unless compelled by storms to make for the land, they keep the sea throughout the whole year, and send their fish ashore by the smaller fishing craft, or by boats of their own, which they keep on board for that purpose.

Shipwrecks.

The number of Chinese ships lost at sea is very great; and it was in consequence of the frequent shipwrecks experienced by the vessels, which were employed in transporting the taxes, or tenth of the produce, from the ports of the middle and southern provinces to the northern capital, that the Imperial canal was projected and executed. The whole awkward construction of the large trading vessels, and especially the great height of their upper works, render them very ill adapted to encounter those violent tempests, which occur in the Chinese seas, and which are called in their language Tay-fung. "Were it possible," said a commander of an East Indian ship to Mr Barrow, when describing the fury of these dreadful hurricanes, "to blow ten thousand trumpets, and to beat as many drums, on the forecastle of an Indiaman, in the height of a Tay fung, neither the sound of the one nor the other would be heard by a person on the quarter-deck of the same ship." These heavy gales prove fatal to such vast numbers of the Chinese vessels, that ten or twelve thousand persons from Canton alone are supposed to perish annually by shipwreck. Hence, when a merchantman leaves that city upon a voyage to foreign parts, it is considered as an equal chance, whether it shall be lost or return; and when the event is prosperous, a general rejoicing takes place among the friends of those who had embarked in the hazardous enterprize.

MONEY AND WEIGHTS.

The ancient money of China is said to have been chiefly shells; but very little can be known on the subject, as the Chinese themselves affirm, that the Emperor Shee-hoang-tee destroyed all the coins, as well as books and other monuments of preceding times. In the year 160 before Christ, the Emperor Ven-tee first permitted the indiscriminate coinage of money by private individuals; but Kao-tsoo, founder of the dynasty of Tang, A. D 619, was the first who regulated the weight and impression of the current coin. The Chinese currency has consisted, at different times, in copper, tin, lead, iron, baked earth, shells, and even paper, according to Marco Polo; but the two latter were soon abolished; and though, in consequence of a scarcity of copper, the Emperor Hong-voo again attempted to bring it into use, A. D. 1368; the Chinese could never be induced to exchange their bullion and property for so unsubstantial an equivalent.

Coin.

Gold is regarded as an article of traffic; but silver and copper form the present currency in China. The silver, however, is never reduced into the shape of coin, but is cast or cut in the form of bars or plates, of different sizes, which, like the Roman *as*, or the Hebrew shekel, are valued according to their weight; and, while the larger bars are employed in paying the more considerable sums, the smaller are cut down into minute portions, according as circumstances require. Hence, a Chinese is always provided with a pair of scissars, a pair of scales, and a set of weights, for the purpose of preparing on the spot the necessary value in bullion. The mode of reckoning the value of silver, is by the number of hundredth parts of alloy which it contains; thus, silver of $\frac{99}{100}$, is that which, in one ounce, has only $\frac{1}{100}$ part alloy. The current silver is from $\frac{98}{100}$ to $\frac{91}{100}$, or even lower, according to circumstances. The government, however, receives nothing but pure silver; and hence, in making any payment to the state, three or four ounces must be added to every hundred, according to the quality of the metal.

There is strictly speaking, therefore, no other coin in China, but of copper; and this is restricted to one denomination, viz. a *Tcheng*, which is scarcely equivalent in value to the third part of a farthing of sterling money. It is a round coin, about $\frac{9}{10}$ of an inch in diameter, with a square hole in the middle, the name of the emperor on one side, and two Tartar words on the other; weighs one *tsien* and two *fen*, and is equivalent to the $\frac{1}{1000}$ part of a tael, or ounce of silver, supposing each of them to be of the standard quality. This copper coin is melted, and not struck; is mixed generally with some inferior metal, chiefly toutenago,* which renders it remarkably brittle, and of a whitish colour; but the government, which has the property of all the mines in the empire, takes great care never to suffer the price of copper to fall so low, as that a profit might be made by counterfeiting the current coin; nor to rise so high, as to endanger the melting of the copper money for articles of manufacture. They are careful also to maintain a due proportion between the quantity of silver and copper in circulation; by making all their payments for a time in silver, when that metal is become scarce, or in copper, when the reverse is the case.

---

* Toutenago, or tintenac, is generally considered as a kind of brittle calamine, chiefly composed of zinc and copper; but M. De Guignes contends, that its properties (especially that of imparting to copper a white colour, and rendering it less liable to verdigrease,

The Chinese count by Leang, tsien, and fen, or by taëls, mas, and condoreens, according to the Portuguese, which are only different names for the same pieces.

Table of Chinese Money.

	Sterling.
10 Tcheng, or cas, or deniers = one condoreen or fen	= $\frac{4}{5}$*d.*
10 condoreen or fen = one mass or tsien =	8*d.*
10 mas or tsien = one taël or leang =	6*s.* 8*d.*

Europeans at Canton generally make and receive payments in Spanish dollars, which are about 4s. 6d. sterling in value, and in quality about $\frac{94}{100}$, though accepted by the He-poo, or collector of customs, only at the rate of $\frac{91}{100}$. Most of the money of other nations, received in China as payment, according to its weight and quality, is afterwards melted down, and converted into articles of luxury, or useful utensils; and it is said, that no nation in the world is better acquainted with the value of the precious metals, or more ingenious in drawing them out to the greatest degree of thinness.

Interest of money.

The rate of interest in China, even as authorised by government, is extremely high, varying from 12 to 18, and even to 36 per cent. Among the various conjectures, which have been proposed as to the reasons of so exorbitant an interest being permitted, the most rational seems to be, that the legislature has thus wished to prevent the possessors of money from having any inducement to make great purchases in land, which might derange the whole system of their policy and administration. Foreigners in Canton lend to the Chinese upon the security of property, at 12 or 18 per cent.; and, if more is ever given, it is rather by way of a *premium* or *bonus*. There are in every city, numerous shops or offices, called Tang-pan, which lend money upon interest, even to unknown individuals, upon articles, being lodged in pawn; and that persons may have access to those offices without being publicly seen, they are generally behind the street, or in some back lane, to which an inscription in the front or main street gives a direction. The Tang-pan, after having estimated the article offered in pawn, lends a sum of money, generally to the amount of one third of the value, and delivers to the borrower a numbered ticket, specifying the article pawned, the value fixed upon it, the sum advanced, the rate of interest, (generally in these cases 18 per cent.) and the term of agreement. Upon presenting this ticket, and repaying the sum with the interest, the article is returned; or the article itself may be retained at the value put upon it, as part of the payment. These tickets may be presented by any person, to whom they may be entrusted or made over by the original borrower; but, if not produced at the time specified, the proprietor loses all right to the pledge, which the Tang-pan then applies to his own benefit.

Weights.

The weights in China vary in different quarters, perhaps to the amount of five pounds more or less in every hundred; but the weights, used by the tribunal of finances, by which every thing due to government is weighed, are the acknowledged standard. Besides the Chinese names for the different denominations, there are corresponding terms in use among Europeans at Canton, which are also given in the following

Table of Weights.

10 Lee or Tcheng = one Condoreen or Fen,
10 Condoreen or Fen = one Mas or Tsien,
10 Mas or Tsien = one Taël or Leang,
10 Taëls or Leang = one Catis or Kin, or 1 lb.
100 Catis or Kin = one Pic or Tan, or 1 cwt.

Long measure.

There is some variation also in the Chinese measures of length, especially in the foot; which is represented by some authors as a few lines longer, and by others as a few lines shorter than the English foot. The Chinese foot or Cobb, or Tche, is divided into ten Tsien, corresponding to inches, and these into ten Fen, nearly equivalent to lines.

Table of Measures of Length.

10 Fen or lines = one Tsien or inch
10 Tsien or inches = one Tche or Cobb
10 Tche, or feet = one Tchang

TRADE.

Trade is not much honoured or encouraged in China. The merchant, who carries on the inland commerce of the country, is ranked far beneath the poorest husbandman; and the man, who engages in foreign traffic, is accounted very little better than a vagabond. The trader, in short, is looked upon as the lowest character in the empire, as a person who will cheat whenever he has the opportunity, and as one whose business consists in creating and supplying artificial wants.

Home Trade.

The home trade alone is regarded as necessary, and as deserving the protection of the government. It consists in the interchange, between the different provinces, of the various goods and manufactures, which they severally produce; and no nation in the world has done more than the Chinese for the establishment and prosperity of an extensive inland commerce. The natural advantages of their country, which is traversed by a multitude of rivers in all directions, have been improved to the utmost; and by the construction of canals and boats of every size and form, the conveyance of every article of merchandise has been facilitated in a manner altogether unexampled. A trader can pass his boat with his goods from one extremity of the empire to another, by paying a small transit duty to the state, and a few tolls upon the different canals and rivers, for the repair of bridges, flood-gates, embankments, &c. This home traffic may be said to be carried on chiefly by barter; and employs such an amazing quantity of small-craft of every description, that it has been calculated to equal in number and tonnage the whole floating vessels in the rest of the world. The principal productions of the different provinces, which forms this commerce, have already been enumerated under the first head of this article, viz. the description of the country; and we may only here remark, that, even in their dealings with each other, the Chinese exercise the utmost degree of distrust, and practise every species of imposition. Of the multitudes of buyers and sellers who crowd the large cities of China, it has been said, that the one half are employed in over-reaching the other. But of this every one is expected to be aware; and their common saying, therefore, is, that it is not the merchant who cheats, but that it is the buyer who cheats himself.

Foreign commerce.

Their foreign commerce is extremely limited; and the

---

while zinc on the contrary communicates to copper a golden colour, and makes it more subject to verdigrease) demonstratively prove that zinc is not the base of toutenago, which he affirms to be rather a compound of iron, lead, and bismuth, which last is known to have the property of whitening copper.

prevailing prejudices of the people, as well as the uniform policy of the government, are adverse to its increase. The Chinese consider their own country as so superior to all others, that they are very reluctant to leave it, even in the prospect of gain; and they have so thorough a contempt for all other nations, that they regard as infamous characters, all those who go to make a fortune among foreigners and barbarians. Those, who do venture abroad for purposes of traffic, are bound to return in a limited time. Those, who remain in foreign countries, are looked upon as outcasts from the empire; and should they suffer any injury or calamity, the government pays no attention to their case. Those, who embark in European vessels upon mercantile speculations, must do so with the utmost secrecy, and also guard against a discovery upon their return, as they would then be pillaged by the mandarins and soldiers, as lawful spoil, without the possibility of procuring any redress.

Foreign trade by land.

Their principal foreign trade by land is carried on with the Tartars and Russians. The former branch of traffic is limited chiefly to an exchange of considerable quantities of coarse tea, for horses, to supply the deficiencies which occur in the ranks of the cavalry. The latter is more extensive; but has been subjected to various alternations and interruptions in its progress. It commenced about the period of the invasion of China by the Mantchoo Tartars; and was first attempted by a governor of Tobolsk, who sent persons of confidence to Pekin, in aid of his commercial plans. In consequence of the opening which was thus effected, a number of Russian and Siberian traders united in 1670 in forming a caravan for Pekin, which succeeded so well as to encourage new companies, and to attract numbers of adventurers. The Chinese government soon became alarmed by these advances of a powerful neighbour, and erected a chain of forts along their northern frontiers, which gave rise to a succession of slight hostilities between the two nations. At length, in 1689, by the mediation of Fathers Gerbillon and Pereira, acting by the authority of the Chinese Emperor Kang-hee, the two courts entered into a treaty of peace and perpetual alliance, which was signed at Nertschinsk, and engraved on two pillars at their respective frontiers. A free commerce was thus permitted to all the subjects of these two extensive empires, who were furnished with passports from their respective governments; for which privilege, Russia made several important concessions, especially the liberty of navigating the river Amour, as far as the Eastern Sea. In 1692, Peter the Great commissioned Isbrand Ives, a Dutchman in his service, to request from the court of Pekin the same privileges for caravans, which the late treaty granted to individuals. This embassy proved successful in procuring the consent of the Chinese government; and as the court of Petersburgh reserved to itself the right of sending these caravans, the whole profit of the trade was turned from the private subjects to the public treasury of Russia. The journey of these caravans occupied a period of three years. Caravanseras were appointed at Pekin for the exchange of the commodities, and for the residence of the Russian merchants, whose expences, during their stay in the capital, were defrayed by the Chinese emperor. Independent, however, of those caravans, a secret commerce was carried on by individuals, through the agency of the Mogul Tartars. In consequence of the drunkenness and misconduct of some Russians, in the midst of the Chinese capital, a misunderstanding originated between the two countries, which had nearly annihilated this commercial intercourse; but the Chinese were pacified by the embassy of Ismäiloff, a captain in the Czar's life guards; and Laurent Lange remained at Pekin, under the denomination of agent to the Russian caravans, with a view to prevent the recurrence of similar disorders. Upon the subsequent departure, however, of this resident, the Russians renewed their turbulent behaviour; and, by the refusal of the court of Petersburgh to deliver up some Tartar hordes, who had become tributary to the Czar, the Chinese government was so much offended, that every Russian was ordered to leave the empire, and all further communication was prohibited. In 1727, Count Ragouzinskoi, an ambassador on the part of Russia to the successor of Kang-hee, succeeded in once more establishing a commercial intercourse between the two nations; and, at the same time, executed a new treaty, fixing definitively the boundaries of the two empires, and subjecting the traders to such regulations as appeared calculated to prevent the recurrence of discontents on either side. The court of Petersburgh was thus permitted to send a caravan to Pekin once in three years; and the number of merchants composing it, was limited to 200. It was farther stipulated, that, upon their arrival on the frontiers of China, they should inform the emperor of their approach, that a Chinese officer might be appointed to escort them to the metropolis; but that no private individual, unconnected with the caravan, should attempt to enter the Chinese dominions, or to trade within the territories of the Moguls. For the intercourse of private traders, however, two places were assigned on the confines of Siberia, where their merchandise should be deposited, viz. Kiakhta and Zurukhaire, or as the Russians call it Näimatschinn, upon the left bank of the Argoun. Notwithstanding all those solemn agreements and stipulations, continual impediments were excited by the violent passions or dishonest practices of the parties concerned in this commercial intercourse; and, in the space of 26 years, only six caravans were fitted out from Russia to China. Many grievances also were alleged by the court of Pekin against that of Petersburgh, especially in protecting the Kalmuck Tartars and Tongusians in their emigrations towards the Russian territories, and evading all the demands and remonstrances of the Chinese government on the subject. Upon the accession of Catherine II. to the throne of Russia, these disputes were amicably terminated; and the public monopoly of the Chinese trade was renounced, in favour of her subjects in general. Notwithstanding occasional interruptions, by the fickleness of the Tongusians, in withdrawing from the protection of the Russians to their former sovereign, the emperor of China, the merchants of the two countries gradually fell into a closer intercourse, and trade became remarkably brisk and active. Russian factories multiplied at Kiakhta, which became a large and fortified place; and Chinese traders resorted, in considerable numbers, to Zurukhaire. Commissaries on each side presided at the exchange of the commodities; and the Mogul language was employed in the contracts made by interpreters. In these bargains, the Chinese are said to have had a decided advantage, to have traded more in a body, and with a greater degree of circumspection, and to have found means to discover the real value of the Russian articles, while they had the art to sell their own, at the price which they chose to fix at first. Tea particularly is sold, at these trading stations, at so high a price, that the purchasers frequently are unable to sell it again so low as the merchants of Petersburgh, who procure it from England or Holland, and who can send it to be sold at Okotsk at 16 rubles per pound. To indemnify themselves in this traffic, the Russians use all means in their power to raise the price of their furs, of which the Chinese are extremely fond; but they are seldom able to outdo these traders in cunning and caution. In this trade the Russian articles are chiefly furs, cloths, hardware, and live cattle, such as horses, camels, &c.; and the Chinese commodities are silk, cotton, porcelain, rhubarb, musk, &c. By a calculation of exports and imports at Kiakhta in 1777, the amount of this commerce between Russia and China was estimated at £573,656 sterling; and including the contraband trade, which is said to be very considerable, and making allowance for the deficiencies of that year, which is said to have been less abundant than the preceding, the gross amount may be calculated at £800,000 sterling. It has greatly declined, however, since that period; and about the year 1788, was completely at a stand, waiting for the confirmation of a new treaty. It is the opinion of M. Lesseps, from whose travels in Kamtschatka the above information is derived, that the taxes and restrictions upon the traders would require to be greatly reduced; and that it would be the interest of the Russians, instead of pursuing this overland traffic, to fit out ships from Okotsk or Kamtschatka, and to trade directly with Macao or Canton.*

Foreign trade by sea.

The foreign trade of the Chinese, as carried on by their own shipping, is extremely limited; and the equipment of vessels for that purpose is confined to the three ports of Canton, Emouy, and Ning-po. They generally sail to Japan in the month of May or June, with a monsoon from the south-east, and return in October by favour of the north winds. In this trade, they export rhubarb, ginseng, silk-stuffs, strings for musical instruments, eagle and sandal wood, leather, cloth, and sugar; and bring back pearls, gold, red-copper, sword-blades, paper, and varnished articles: making great profit, especially upon their sugar, and supposed to gain upon the whole *cent. per cent.*

Japan.

Manilla.

Their trade to Manilla is accounted only about one-half as gainful, and consists in exchanging silk-stuffs and stockings, embroideries, tea, porcelain, varnish, and drugs; for piastres, rice, birds' nests,† pearls, and dyeing materials.

Batavia.

To Batavia their traffic is more considerable than to any other quarter, and is greatly encouraged by the Dutch. They sail thither in the month of December, with cargoes of porcelain, tea, toutenago,‡ copper vessels, rhubarb, and other drugs; and take, in return, silver, tin, pepper, nutmeg, cloves, tortoise shells, birds' nests, sandal wood, red wood, amber, and European cloths.

Cochinchina.

To Cochinchina they export linen and woollen stuffs, and receive in exchange, gold, areca, and cinnamon.

Malacca.

From Malacca, Siam, and Cambodia, they bring home resin, tin, camphor, birds' nests, elephants' teeth, and the horns of the rhinoceros.

Commerce with European traders.

That species of the foreign trade of China, which is carried on by the ships of other nations, is confined entirely to the port of Canton; and may be said to be a branch of traffic, which is barely tolerated by their government. The court of Pekin, indeed, has frequently indicated a disposition to shut the port of Canton, and of consequence all their other ports, against foreign vessels; and, except the loss of the customs, drawn by the emperor, and the injury, which the city of Canton would sustain, it has been questioned, whether the Chinese nation in general would lose much by the exclusion. The principal articles, which they receive by this European commerce, and which may be viewed as most approaching to necessaries, are *tin*, which is chiefly employed in making tea boxes, and which would become less necessary were the European demand for that article suspended, or which they might procure as formerly from Batavia and Malacca; *lead*, which is used chiefly for the same purpose, and which would become equally unnecessary from the same cause; *spices*, of which the Chinese do not make great use; *cotton*, of which they could themselves produce abundance, by resuming the culture of the cotton plant, instead of the tea-tree, which they have in a great measure substituted in its place; and *broad cloths*, which are principally used by the wealthier classes, but for which they might easily find proper substitutes.

On the other hand, nothing but the importance of the trade to Europeans, especially the valuable and universal commodity of tea, could induce the merchants of other countries to tolerate the usage, which they experience at Canton, from the very lowest officers of the Chinese government. They are not only received with the utmost indifference, but are often treated with the greatest rudeness, and daily exposed to the grossest extortions. They are compelled to trade with a limited number of Chinese merchants, seldom exceeding eight, who have the sanction of government to treat with foreigners; and who are responsible, on their part, for the conduct of those with whom they have dealings. With these men, and their deputies, the strangers transact business in a kind of mixed jargon of English, Portuguese, French, and Chinese; and, beyond this communication, they have scarcely one indulgence or privilege of any kind. They cannot extend their walk a few hundred yards beyond the limits of the factory, without danger of insult; and are always watched and suspected at every step which they take. The very meanest of the natives are in a manner prohibited from serving them; and almost account themselves degraded by their employment. The import and export duties, ought, by the law of the country, to be levied according to the value of the cargoes or size of the vessels; but are, for the most part, arbitrarily fixed at the fancy of the collector. The Chinese government, indeed, are ready to punish, with confiscation of property, those officers, who are guilty of extortion, and have often shewn great justice and moderation in cases, which were duly represented; yet its vigilance is generally evaded, and its threatenings silenced by the potency of presents; while the foreign merchants, from their ignorance of the language, are unable to bring their grievances to the knowledge of the viceroy, which it would be vain to attempt to transmit through the petty officers or Hong merchants, who are all interested in keeping such things from the ear of their superiors.

These Hong merchants, also, though generally distinguished by the liberality and accuracy of their dealings, have the foreign trader wholly at their mercy, as they possess the complete monopoly of the commerce. They alone are entitled to receive the imported goods, and to furnish the return cargoes. With them the foreigner must of necessity treat; and they are almost equally obliged to insist upon enormous profits, as they are expected to pay for their privileges by frequent and magnificent presents to the superior officers at Canton; and these again must share the spoil with the emperor and his chief ministers at Pekin. Many of these officers at Canton arrive from the capital sufficiently poor; and in the space of three years return thither with immense riches. The various curiosities, jewellery, and other articles of English manufacture, which have been observed in the different imperial palaces, and all of them presents from Canton, exclusive of similar valuables, in the possession of the higher mandarins, have been estimated at a sum equal to two millions sterling.

---

* Further particulars of this commerce may be found in Coxe's *Russian Discoveries*, p. 197; and in Pallas's *Reise*, vol. i. p. 232.

† These nests are made by a species of swallow, and are composed of sea worms of the mollusca class, cemented together and fastened to the rocks by means of a slimy matter which issues from the bill of the bird, or which, as others suppose, it collects from the surface of the water. They are small and tough, resembling the half of a lemon-rind; and those are accounted the best, which are white, clean, and free from feathers.

‡ See p. 297. Note.

Commercial tricks of the Chinese.

Of the refined knavery, and undisguised extortions practised by the Chinese upon European traders, and even upon one another, the following instances may be given as attested facts, upon the authority of Mr Barrow. "In consideration of the Hindostan, (a ship employed, in the embassy of Lord Macartney) having carried presents for the emperor, an order was issued from court, that she should be exempt from duties, at any of the ports, where she might take in a cargo. It happened that the Hong merchants had already paid the Hindostan's duties with those of the other ships, of which her particular share was 30,000 ounces of silver. The Hoppoo, or collector, was therefore requested to return this sum, agreeably to the order from court; but he refunded only 14,000 dollars, which can be reckoned as little more than 11,000 ounces, observing that so much was the exact amount of the emperor's duties."

"An Armenian merchant brought a large pearl to Canton, in the expectation of making his fortune. Its size and beauty soon became known, and attracted the attention of the officers and the merchants, who paid their daily visits to the Armenian, offering him prices far inadequate to its value. At length, however, after minute and repeated examinations, a price was agreed upon, and a deposit made; but the Armenian was to keep possession of the pearl till the remaining part of the purchase-money should be ready; and, in order to obviate any possibility of trick, the box, in which it was kept, was sealed with the purchaser's seal. Several days elapsed without his hearing any thing further from the Chinese; and, at length, the time approached, when all foreign merchants are ordered down to Macao. The Armenian in vain endeavoured to find out the people, who had purchased his pearl; but he contented himself with the reflection, that, although he had been disappointed in the main object of his journey, he still had his property, and that the deposit was more than sufficient to defray his expences. On reaching his home, he had no longer any scruple in breaking open the seal; but his mortification may easily be supposed, in discovering that his real pearl had been exchanged for an artificial one, so very like as not to be detected, but by the most critical examination."

"I bought of a blind man in the street," says M. Osbeck, "a Camellia Japonica, which had fine double white and red flowers. But, by farther observing it in my room, I found, that the flowers were taken from another tree, and one calyx was so neatly fixed in the other with nails of bamboo, that I should scarce have found it out, if the flowers had not begun to wither. The tree itself had only buds, but no open flowers. I learned from this instance, that whosoever will deal with the Chinese must make use of his utmost circumspection; and even then must run the risk of being cheated."

"One of my countrymen," says the same author, "can testify this, who buying some chickens, the feathers of which were curiously curled, found, in a few days time, the feathers growing straight, and that his chickens were of the most common sort. The Chinese had curled the feathers up like a wig, a little before he was going to sell them. This is an instance of a Chinese who spares neither time nor pains, if he can only gain money, whether by fair or fraudulent means."

"Sometimes you think you have bought a capon," says Grosier, "and you receive nothing but skin; all the rest has been scooped out, and its place so ingeniously filled, that the deception cannot be discovered, till the moment you begin to eat. The counterfeit hams of the Chinese have often been mentioned. They are made of a piece of wood, cut in the form of a ham, and coated over with a certain kind of earth, which is covered with hog's skin. The whole is so curiously painted and prepared, that a knife is necessary to detect the fraud."

The contempt testified by the Chinese towards foreign traders proceeds not merely from their notions of national superiority, and their low views of the mercantile occupation in general; but is no doubt greatly confirmed by the knavery and deceit, which are sometimes practised upon their own people, by the merchants of Europe. Notwithstanding all their acuteness and caution, they have often been cheated with gaudy watches, and similar articles of indifferent workmanship, purposely fabricated for the Chinese market, and the following instance of English fraud, recorded by Mr Barrow, is not much inferior to those of the Chinese dealers. "One gentleman in the honourable East India Company's employ, took it into his head, that cuckoo clocks might prove a saleable article in China; and accordingly laid in a large assortment, which more than answered his most sanguine expectations. But, as these wooden machines were constructed for sale only, and not for use, the cuckoo clocks became all mute, long before the second arrival of this gentleman with another cargo. His clocks were now not only unsaleable, but the former purchasers threatened to return their's upon his hands, which would certainly have been done, had not a thought entered his head, that not only pacified his former customers, but procured him also other purchasers for his second cargo. He convinced them by undeniable authorities, that the cuckoo was a very odd kind of bird, which sung only at certain seasons of the year; and assured them, that, whenever the proper time arrived, all the cuckoos, they had purchased, would once again tune their melodious throats."

English tricks.

Exported articles.

The principal articles, exported from China in the commerce with Europe, are:—

Porcelain, of various descriptions.

Tea, of which the principal kinds are,

	taels.
Vooy, Booy or Bohea, at from	12 to 15 per pic.*
Song-lo	24—26
Cong-foo	25—27
Sao tchon	40—50
Pekao	34—60
Hay-suen	50—60
Tchu	65—70
Sugar	4—6
Sugarcandy	7—15,

---

* The pic is equal to 100 Chinese pounds of 16 taels or ounces.

	taels.	
Cinnamon	12—24	per pic.
Camphor	20—28	
Musk	30—37	per catis or lb
Ginseng	10—18	per tael or oz.
Turmeric	3— 4	per pic.
Rhubarb	36—40	
Dragon's blood	25—40	
Anise-seed	9—10	
Alum	2— 3	
Borax	20—30	
Toutenago	6— 7	
Quicksilver	50-150	

Gold, which as an article of commerce is $\frac{88}{100}$ in quality, and in the form of plates or ingots, of which that from Tonkin and Cochinchina is the best, and is generally formed into long square pieces.

Nankeens, of which there are two kinds, the one in broad pieces, 18 cobbs in length, 100 of which are sold for a price from 66 to 89 taels; and the other in narrow pieces of 14 cobbs, sold from 34 to 65 taels per hundred.

Imported articles.

The principal articles of importation are,

		taels.	
Amber	from	14 to 22	per pic.
Areca nut		2½— 5	
Asafœtida		6— 8	
Azure		18—36	
Cotton of Surat		9—13	
Tin		14—16	
Wax		20—40	
Clove buds		102-160	per catis or lb
Cochenille		200-600	per pic.
Tortoise shell		50-105	
Copper from Japan		12—20	
Gold and silver thread		15—30	
Nutmeg		100-400	
Ebony		11½—3½	

Pepper from Bencoolen or Batavia, at from 11 to 15 taels per pic; from the coast of Malabar, at 14 to 16.

Sandal wood, of the best quality, sells from 20 to 30 taels per pic; of the second, from 12 to 25; and of the third, from 10 to 16.

Tobacco, from the coast of Brasil, at 70 piastres per pic, even for the inferior kinds, and in 1797 rose to 150 piastres.

Ivory sells from 20 to 72 taels per pic, according to the size of the tusks.

Camphor from Borneo, of the first quality, from 1100 to 2000 taels per pic; of the second quality, from 600 to 1300; of the third quality, about 400.

Coral, in small grains about the size of a pea, sold in 1797 at 40 to 50 taels per catis or lb; but in pieces of a tael and a half in weight, and of a rose colour, at 1400 piastres per piece, and of two taels in weight at 2000.

Steel, which sells best in China, when in pieces of nine or ten inches in length, or about one inch square, at four to seven taels per pic.

Ginseng of Canada, which formerly sold at 500 taels per pic; but, having now lost its quality and character,* only brings from 30 to 45, which scarcely pays the duty upon it, and it can therefore be sold only as smuggled goods.

Birds nests † as articles of food, sell at a price from 1600 to 2500 taels per pic for those of the first quality, from 900 to 1800, for the second; and from 800 to 1000, for the third.

Opium, which in 1810 was more strictly prohibited by an edict of the government, has generally been secretly sold at a greater or less price, according to its quality, and the quantity in the market; but almost always with great profit.

Rabbit and Otter skins, and other furs, were wont to be in considerable demand, but the market has frequently been overstocked.

Glass, mirrors, pearls, gold watches, are all very gainful articles of merchandise at Canton.

Manner of proceeding in the trade at Canton.

As soon as a foreign vessel is moored in the roads of Macao, the Captain must go ashore to give information of the nation to which he belongs, of his own name and that of his ship; and then procures a pilot, who is intrusted with the further navigation of the vessel. When the trader has arrived at the Bocca Tigris, or mouth of the river of Canton, the mandarins send a soldier on board, who remains in the ship till it reaches Wampoo, and till the boats of the custom-house at that place are fairly along side. From this period, no article enters or leaves the ship without being first examined, and having paid the duties, except provisions, which pass free. At this place the ships generally begin to unrig; and the Chinese soon erect on the shore sorts of shades or tents of bamboo covered with matting, for the reception of the rigging, or the accommodation of the sick on board. About three or four days after the arrival of the vessel, the Ho-poo, or collector of the customs, comes on board with the Hong merchants and interpreters; and proceeds to take the measurement of the ship before permission is granted to land the cargo. This measurement is made first along and then across the deck, and the amount of these two quantities, multiplied together, is the result required. If this surface exceeds 154 Tchang, each of which is equal to ten Chinese feet, the vessel is ranked as a first rate, and pays for each Tchang seven taels four mas, four condoreens, and eight deniers; if it exceeds 120 Tchang it is accounted a second rate, and pays for each of these measures, six taels, eight mas, four condoreens; if below 120 Tchang, it is regarded as a third rate, and pays for each, four taels, seven mas, eight condoreens, eight deniers. Besides the duty upon this measurement, every foreign trading vessel indiscriminately pays to the Ho-poo by way of present 1950 taels=L. 650; and hence, in the commerce with China, it is evidently more advantageous to employ one large ship, than two of a smaller tonnage. The articles on board are then conveyed to Canton in Chinese boats, at the expence of the foreign trader; and being carefully noted, as they are put into these boats, are marked at every custom-house on the route, and finally examined at Canton in the European factory, or in the warehouses of the Hong merchants; but it is recommended to the foreigner to have one or two sailors from the vessel on board of each boat, both in loading and unloading, as the Chinese are remarkably dexterous in committing depredations, and substituting false chests or bales in the place of those which they purloin. The money for the purchase of the cargo is sent up in the ship's boat; and as none is allowed to be again withdrawn, when once landed in the country, it is necessary to retain on board whatever is not intended for this purpose. Copper and iron are subject to the same regulation; and, though destined solely for the use of the vessel, yet, if once sent ashore, are not easily recalled on board.
